Variants within the MMP3 (rs679620) and TIMP2 (rs4789932) genes have been associated with the risk of Achilles tendon pathology (ATP) in populations from South Africa and Australia. This study aimed to determine whether these variants were associated with the risk of ATP in British Caucasians. We recruited 118 cases with ATP, including a subset of 25 individuals with Achilles tendon rupture (RUP) and 131 controls. DNA samples were isolated from saliva and genotyped using qPCR. For the MMP3 rs4789932 variant we found a significant (p = 0.038) difference in the genotype distribution frequency between males with ATP (CC, 39.4%; CT, 43.7%; TT, 16.9%) compared to male controls (CC, 20.7%; CT, 59.8%; TT, 19.5%). We also observed a difference in the TIMP2 rs4789932 genotype distribution between males with rupture compared to male controls (p = 0.038). The MMP3 rs679620 GG genotype was found to be overrepresented in the Achilles tendon rupture (RUP) group (AA, 24.0%; AG, 32.0%; GG, 44.0%) compared to controls (AA, 26.7%; AG, 54.2%; GG, 19.1%). In conclusion, the CT genotype of the TIMP2 rs4789932 variant was associated with lower risk of ATP in males. Furthermore, we revealed differences for both variants in genotype distribution between the RUP and control groups, the sample size of the RUP group was small and confirmation would be required in additional cohorts. Finally, although both the TIMP2 rs4789932 and MMP3 rs679620 variants tentatively associated with ATP, there were differences in the direction of association compared to earlier work.

1. Introduction

Achilles tendon pathology (ATP) is an umbrella term that refers to both Achilles tendinopathy (TEN) and Achilles tendon rupture (RUP). ATP is a debilitating condition and most cases are related to overuse injury caused by chronic or acute exposure to repetitive micro-traumas (Kvist, 1994). Several intrinsic and extrinsic risk factors for ATP have been reported, and an increasing number of association studies have demonstrated that genetic variants can predispose to the condition (Raleigh and Collins, 2012).

The extracellular matrix (ECM) within a tendon consists of collagen fibrils, proteoglycans, glycoproteins and glycosaminoglycans (Sharma and Maffulli, 2005). In addition to structural proteins, non-structural proteins and enzymes contribute towards homeostasis by constantly remodelling the ECM (Magra and Maffulli, 2005). MMP3 belongs to the family of metalloproteinases (MMPs) which are known for their role in controlling the ECM integrity by catalytically degrading structural proteins including laminin, fibronectin, and various types of collagen (Somerville et al., 2003; Birkedal-Hansen et al., 1993). MMP3 is known to stimulate the activity of other MMPs which eventually contribute towards the catalysis of other proteins within the ECM (Toth et al., 2003). However, MMP3 mRNA levels have been consistently shown to be lower in ATP samples when compared to the controls (Ireland et al., 2001; Alfredson et al., 2003). Tissue inhibitors of metalloproteases (TIMPs) are known for their role in inhibiting the activity of metalloproteinases by interacting with the MMP active site (Young et al., 2002). Although TIMP2 does not inhibit the activity of MMP3, it inhibits the activation of MMP2 which works in parallel with MMP3 to activate MMP9 (Toth et al., 2003). Therefore, by limiting the activity of MMP2, TIMP2 is considered to indirectly reduce the impact of MMP3 activity.

Recent work has shown that the rs679620 single nucleotide polymorphism (SNP) within the MMP3 gene and the rs478992 SNP within the TIMP2 gene were risk factors for ATP in a South African (Raleigh et al., 2009) and a combined South African and Australian cohort respectively (El Khoury et al., 2013). However, as genetic predisposition to multifactorial phenotypes is often population specific, we wished to...
ascertain whether these polymorphisms were also risk factors in a recently recruited British population.

2. Materials and methods

One hundred and eighteen (47 females and 71 males) British Caucasian patients diagnosed with Achilles tendon pathology (ATP) and 131 (49 females and 82 males) asymptomatic British Caucasian controls (CON) were recruited for this case–control genetic association study. All case participants were recruited from The County Clinic, Northampton, UK between 2011 and 2014. A suitable control population of physically active individuals with regular exposure to lower limb exercise (minimum 2 h/week of high intensity exercise) and no history of Achilles tendon pathology, were recruited from sports clubs within the East Midlands area. All participants gave written informed consent, according to the Declaration of Helsinki, and completed a medical and injury history questionnaire. All participants with ATP were diagnosed by the medical professional and co-author WJR based on the clinical criteria reported in previous studies (Mokone et al., 2005; September et al., 2009). For patients with tendon ruptures, the clinical diagnosis was corroborated in most cases (88.0%, n = 22) by either imaging (60.0%, n = 15) and/or surgical observation (52.0%, n = 13). Our recruitment and experimental protocols were approved by the University of Northampton Research Ethics Committee.

The ATP group consisted of 93 (39 females and 54 males) participants with chronic Achilles tendinopathy (TEN), and 25 (8 females and 17 males) participants with Achilles tendon rupture (RUP). Patients with chronic Achilles tendinopathy (TEN) were diagnosed as suffering from either non-insertional (n = 51, 54.8%), insertional tendinopathy (n = 28, 30.1%), or both (n = 14, 15.0%). Achilles ruptures were categorised as full or partial ruptures. For the purpose of analysis, participants diagnosed with Achilles tendinopathy who later sustained an Achilles rupture (n = 12), were included in the RUP group. At the time of recruitment participants in the ATP group were generally healthy with the exception of 18 (15.2%) individuals who were on medication for different cardiovascular conditions. We also report that 34 (28.8%) ATP cases reported a history of tendinopathy in a tendon other than the Achilles tendon, 46 (38.9%) reported a history of ligament injury.

Saliva samples were collected from each participant using Oragene™ OG-500 tubes (DNA Genotek, Ontario, Canada). DNA was extracted according to the manufacturer’s protocol using a PT-L2P lysis solution. DNA samples were genotyped for the MMP3 rs679620 and TIMP2 rs4789932 gene variants using fluorescence-based TaqMan® Custom SNP Genotyping Assays (Applied Biosystems, Foster City, CA, USA). The qPCR reactions contained probes and primers and PCR mastermix containing AmpliTaq DNA Polymerase Gold (Applied Biosystems, Foster City, CA, USA) in a total reaction volume of 6 μL. PCR was performed on an Applied Biosystems StepOnePlus™ real-time PCR system (Applied Biosystems, Foster City, CA, USA). Genotypes were determined following end point fluorescence analysis using Applied Biosystems StepOnePlus™ real-time PCR software Version 2.1. Rox was used as a passive reference and each PCR run included a number of both positive (sample repeats) and negative (water) controls.

Data were analysed using SPSS Version 20 (IBM SPSS, IBM Corp, Somers, NY, USA) statistical programme. A chi-squared (χ²) analysis was used to determine whether significant genotype and/or allele distribution differences existed between CON and ATP groups. An independent t-test was used to establish if any significant differences existed between the participants’ characteristics of the ATP and CON groups and an analysis of variance was used to identity differences in participants’ characteristics when grouped into genotypes. In all analyses significance was accepted when p < 0.05. No adjustment for multiple testing was made due to the rationale described in our previous studies (Posthumus et al., 2011). Hardy–Weinberg equilibrium was determined using Michael H. Court’s (2005–2008) online calculator (www.tufts.edu). We used Quanto software (version 1.2) for power calculations and found that, for our entire cohort, the sample size was sufficient to detect associations with approximately 80% power at the p < 0.05 level with odds ratios of 2.2 and above.

3. Results

The CON and ATP groups were matched for age, height, weight, and body mass index (BMI). However, when the data was stratified according to gender, we found a difference in height (p = 0.023) between the males ATP and CON groups. Males in the CON group were taller than those in the ATP group (Table 1). However, height was not a confounding variable in our analysis as genotypes at both of the loci tested did not associate with height.

The allele and genotype distribution frequencies for the MMP3 and TIMP2 variants are shown in Tables 2 and 3 respectively. We found a significantly (p = 0.021) different genotype distribution frequency of the MMP3 rs679620 variant between the CON (AA, 26.7%; AG, 54.2%; GG, 19.1%) and the RUP (AA, 24.0%; AG, 32.0%; GG, 44.0%) groups. The GG genotype was significantly over-represented among the RUP group (p = 0.009; OR = 3.33; 95% CI 1.35–8.21), whereas the AG genotype was significantly over-represented among the CON group (p = 0.046; OR = 2.51; 95% CI 1.01–6.23). However, the number of patients who presented with ruptures was small and, as such, this result would require confirmation in additional cohorts. In addition, we found a significantly different (p = 0.038) genotype distribution for the TIMP2 rs4789932 variant in male participants between the CON (CC, 20.7%; CT, 59.8%; TT, 19.5%) and ATP (CC, 39.4%; CT, 43.7%; TT, 16.9%) groups. The CT genotype was significantly over-represented within the male CON group (p = 0.004; OR = 2.75; 95% CI 1.38–5.44), whereas the CC genotype was over represented in the ATP group (p = 0.012; OR = 2.49; 95% CI 1.22–5.09). A similar trend in distribution was found between the male CON and RUP groups (p = 0.038).

There was no significant genotypic distribution difference for the TIMP2 rs4789932 variant between the CON and ATP groups within female participants (p = 0.639), or in the combined male plus female group (p = 0.364). Furthermore, we report no genotypic distribution differences for the MMP3 rs679620 variant between the CON and ATP groups (p = 0.413), or between the CON and the TEN group (p = 0.564) (Table 2). We also report no allelic distribution difference for either gene variants between the CON and ATP groups (Tables 2 and 3). All the genotype distribution groups included in this study were in Hardy–Weinberg equilibrium (HW).²

4. Discussion

We have primarily found a significant association (p = 0.021) between the MMP3 rs679620 variant and Achilles tendon rupture, with the GG genotype being over represented in the RUP group compared to the CON group. In an earlier study we found that the GG genotype was a risk factor for Achilles tendinopathy but not Achilles tendon rupture in South Africans Caucasians (Raleigh et al., 2009). The G allele of the rs679620 locus is known to increase MMP3 expression (Foster et al., 2012), as it is in high linkage disequilibrium (LD) with the 5A allele of the rs3025058 variant (Chen et al., 2012). The 5A allele has been reported to up-regulate MMP3 mRNA levels (Ye, 2006). Accordingly, over-expression of the MMP3 gene could increase the risk of tendon degeneration since MMP3 protein plays a role in the breakdown of ECM substrates such as proteoglycan, decorin, and laminin (Birkedal-Hansen et al., 1993). Therefore, an accelerated or excessive MMP3 mediated destruction of some of these ECM components might predispose to tendon rupture. We have also shown that the TIMP2 rs4789932 variant is associated with the risk of ATP in British males. Specifically, the CC genotype was over represented in the ATP and RUP groups compared to an over representation of the CT genotype in the CON group. This finding differs
with an earlier study in which the CC genotype was over represented among controls and the CT genotype associated with ATP cases in a combined Australian and South African Caucasian population (El Khoury et al., 2013). However, although the direction of the association found in this study (CC genotype as risk factor) was opposite to that reported in the earlier work (CC genotype as protective factor), the data might indicate that a complex mechanism underlies the involvement of this locus in the predisposition to ATP. Indeed it has recently been noted that reverse effects in genetic association studies may reveal additional information about a susceptibility locus that was previously unknown. For example, minor alterations in allele frequency between populations, differences in interacting loci, gene, and gene–environment interactions may all contribute to a reverse effect, even in populations that are of the same ethnicity but drawn from different geographic locations (Greene et al., 2009). The reversal effect could also be due to a difference in LD between the associated and the causal variant between different populations of the same ethnicity (Ferreiros-Vidal et al., 2007). Furthermore, it is possible that genes in individuals from different regions undergo local adaptation following geographical and environmental isolation (Tiffin and Ross-Ibarra, 2014; Sexton et al., 2014). This can sometimes be explained by the concept of conditional neutrality where an allele can be neutral in certain locations and risk related in a completely different setting (Fournier-Level et al., 2011). Such effects have been reported in systemic lupus erythematosus, where the PD1.3A allele of the PDCD1 gene associates with risk related characteristics in some European Caucasian populations but it has protective characteristics in others (Ferreiros-Vidal et al., 2007; Ferreiros-Vidal et al., 2004). With relevance to this, the association described in this study was found in British Caucasian males whereas our previous work was conducted in a Caucasian population of both genders recruited from Australia and South Africa (El Khoury et al., 2013).

At present we cannot specifically explain why the TIMP2 rs4789932 variant influences the risk of ATP or Achilles tendon rupture but it is noteworthy that a number of studies have found that TIMP2 expression is altered in tendon tissue under a variety of conditions. For example, Jones et al. (2006) have shown that TIMP2 expression is reduced in human degenerate Achilles tendon compared to healthy tissue. Furthermore, ageing was found to significantly reduce the expression level of TIMP2 in rabbit patellar tendons (Thornton et al., 2013). Hence, a reduction in TIMP2 levels might contribute to tendon degradation since lower levels have been speculated to disrupt the TIMP/MMP balance and adversely alter ECM homeostasis (Pasternak et al., 2010). Interestingly, TIMP2 expression in human ruptured Achilles tendons has been found to increase relative to non-rupture tendon samples (Karousou et al., 2008) and a study in rodents showed that overuse of the supraspinatus tendon was accompanied by an initial decrease in TIMP2 levels followed by a subsequent rise (Attia et al., 2013). This latter observation may well explain the observed decrease in TIMP2 during tendon degradation which apparently takes place at the pre-rupture stage (Jones et al., 2006). Consequently, a rupture may occur at an advanced stage of tendinopathy and thus might be accompanied by an increase in TIMP2 levels.

In summary, this study follows the work previously conducted in South African and Australian Caucasian populations (Raleigh et al., 2009; El Khoury et al., 2013). These earlier studies showed that both the MMP3 rs679620 and the TIMP2 rs4789932 variants associated with ATP in the South African cohort (MMP3 rs679620 variant) (Raleigh et al., 2009) and when both populations were combined (TIMP2 rs4789932 variant) (El Khoury et al., 2013). Our present study in British Caucasians reveals that the association of the TIMP2 rs4789932 variant with ATP and Achilles tendon rupture is only apparent in males. Furthermore, we found that it was carriage of the CC genotype that inferred risk as opposed to the CT genotype in the combined South African and Australian cohorts which inferred risk of ATP but not Achilles tendon rupture. Finally, for the MMP3 rs679620 variant, we found a tentative association between the GG genotype with Achilles tendon rupture but not with tendinopathy per se.

To conclude, although this study did not directly replicate the direction of associations we found in earlier work (Raleigh et al., 2009; El Khoury et al., 2013), the present study confirms the importance of the TIMP2 rs4789932 variant in predicting the risk of Achilles tendon rupture.

El Khoury et al., 2013) it was confirmed that the same loci seemed to modify the risk of Achilles tendon pathology or rupture in some way. This may well reflect the fact that the current work was conducted in a population recruited from a different geographic region compared to our earlier work. In terms of limitations, we must treat these data as tentative findings and remember that confidence in our data would be greater if the work was repeated in a larger cohort. A specific limitation was that sample size was reduced when we conducted gender specific analysis and when we stratified the ATP cohort into the separate sub groups (tendinopathy or rupture). This would result in a reduction in statistical power. Finally, these findings suggest that the risk of ATP phenotypes, associated with the loci investigated, are modified by both gender and geographical location.

Acknowledgements

The authors would also like to thank Professor Malcolm Collins and Dr. Michael Posthumus at the University of Cape Town’s UCT/MRC Research Unit for Exercise Science and Sport Medicine for discussions concerning the questionnaire design. Authors S.M.R. and W.J.R. were co-inventors on patents that were filed on the application of specific sequence variants (rs679620 but not rs4789932) related to risk assessment of Achilles tendinopathy and anterior cruciate ligament injuries.
