Nanoparticles of molybdenum(IV) oxide (MoO₂) and a TiO₂/MoO₂ nanocomposite were synthesised via a continuous hydrothermal synthesis process. Both powders were analysed using XRD, XPS, TEM, and BET and evaluated as active materials in anodes for Li-ion half-cells. Cyclic voltammetry and galvanostatic charge/discharge measurements were carried out in the potential window of 0.1 to 3.0 V vs. Li/Li⁺. Specific capacities of ca. 350 mAh g⁻¹ were obtained for both materials at low specific currents (0.1 A g⁻¹); TiO₂/MoO₂ composite electrodes showed superior rate behaviour & stability under cycling (compared to MoO₂), with stable specific capacities of ca. 265 mAh g⁻¹ at a specific current of 0.5 A g⁻¹ and ca. 150 mAh g⁻¹ after 350 cycles at a specific current of 2.5 A g⁻¹. The improved performance of the composite material, compared to MoO₂, was attributed to a smaller particle size, improved stability to volume changes (during cycling), and lower charge transfer resistance during cycling. Li-ion hybrid electrochemical capacitors using TiO₂/MoO₂ composite anodes and activated carbon (AC) cathodes were evaluated and showed excellent performance with an energy density of 44 Wh kg⁻¹ at a power density of 600 W kg⁻¹.

Keywords: continuous hydrothermal flow synthesis; molybdenum oxide; composite anode materials; pseudocapacitance; supercapattery

1. INTRODUCTION

Energy storage devices have become a major research focus because of concerns over energy security, the intermittency of renewable energy supplies and the negative health effects associated with

air pollution from the burning of fossil fuels [1]. As hybrid and full electric vehicles are developed, they will enable the decarbonisation of the transport sector [2]. The key technology making this transition possible is Li-ion batteries (LIBs), which can be used in both automotive and stationary energy storage applications [3–6]. Typically, a LIB consists of an anode (e.g. graphite), a cathode (e.g. lithium iron phosphate), an electronically insulating separator (glass fibre or polyethylene) and an organic electrolyte containing a Li^+ salt [7]. Because the power densities of LIBs are often limited, electrochemical double-layer capacitors (EDLC) are considered more promising for high-power applications such as regenerative braking [8]. More recently, devices such as Li-ion hybrid electrochemical capacitors (Li-HEC) have been developed as they offer a balance of both moderate power and energy density; these devices typically use activated carbon cathodes and battery-type redox anodes. During the charging of Li-HECs, Li-ions are inserted into the anode active material and anions (e.g. hexafluorophosphate) are absorbed onto the active carbon surface in the cathode (PF_6^- desorption and Li^+ extraction occur simultaneously during discharge) [9]. In contrast to LIBs, both anions and cations are subjected to symmetrical driving forces towards opposite electrodes [10], which means that concentration gradients, which can often limit high power performance in LIBs, are reduced [11].

Nanomaterials are of interest as active electrode materials in high-power LIBs because of their high surface area to volume ratio, which can result in a higher proportion of the charge to be stored on or near the surface, enabling more rapid charge transfer compared to micron-sized (primarily intercalation based) materials with relatively lower surface areas [12,13]. This is particularly important at higher charge/discharge rates. Fast, near-surface Faradaic reactions (also referred to as pseudocapacitive processes) can improve charge storage for devices undergoing rapid charge/discharge; this has been studied for materials such as RuO_2 with aqueous electrolytes or anodes in LIBs for various nano-sized TiO_2 polymorphs (anatase [14], Nb-doped anatase [15], Mo-doped anatase [16], $\text{TiO}_2(\text{B})$ [17], and TiO_2 bronze [18]) as well as for nano-sized MoO_2 [12].

Molybdenum dioxide has been used in anodes for LIBs, both as an intercalation material [19] and as a conversion-type anode [20–25]. As an intercalation material, MoO_2 has a theoretical specific capacity of 209 mAh g^{-1} [26] and as a conversion material (when cycled to potentials below 1.0 V vs. Li/Li^+), it has a theoretical specific capacity of 838 mAh g^{-1} [27]. Due to these properties and the comparatively high abundance and low cost of molybdenum, MoO_2 is of interest as active material for negative electrodes in energy storage devices [28]. However, MoO_2 suffers from dramatic capacity fading when cycled as a conversion anode, due to the gradual deterioration of electrode integrity [29]. The cycling stability of certain conversion electrode materials can be improved by the incorporation of more stable inorganic phases that do not undergo large volume or structural changes [30,31], such as TiO_2 [32–34]. Alternatively, nano-sizing of active materials such as MoO_2 and the use of carbon coatings have been investigated previously to overcome some of the limitations of bulk MoO_2 . Therefore, scalable methods for the fabrication of nanoceramics that allow for the incorporation of other stabilising nanomaterials, or coatings to active nanomaterials, are desirable [12,22,35].

Synthesis processes for making nanomaterials and composites are often limited in terms of their scalability [35]. Synthesis processes for the production of MoO_2 nanoparticles can involve multi-step processes (resulting in inconsistent particle properties) [36], can involve long reaction times [37], or can require multiple energy intensive annealing or processing steps [38]. In contrast to batch or

multi-step processes, continuous synthesis processes can offer advantages such as directly forming products with more precise control over reaction conditions during nucleation and growth.

Highly scalable continuous hydrothermal flow synthesis (CHFS) methods have been used to reproducibly manufacture crystalline nanomaterials [39–41]. In CHFS processes, a feed of supercritical water (typically at 450 °C) is brought in contact with an ambient temperature aqueous solution of metal salt(s) in a well-defined engineered mixer, to bring about the instantaneous formation of nanoparticle metal oxides (via a complex set of reactions that include hydrolysis, decomposition and dehydration processes [42]). In such flow processes, crystalline nanoparticles can be directly made as a water-dispersed slurry at ambient temperatures (see experimental section).

Herein, we describe the direct synthesis of both ultrafine MoO₂ and composite TiO₂/MoO₂ nanoparticles using a CHFS process. CHFS-made TiO₂/MoO₂ nanocomposite-containing anodes showed dramatically improved cycling stability in a Li-ion half-cell compared to the analogous MoO₂ nanoparticles.

2. EXPERIMENTAL SECTION

2.1. Synthesis

The synthesis of phase-pure anatase TiO₂ via CHFS has been described elsewhere by the authors [15,16]. Herein, MoO₂ nanoparticles and a TiO₂/MoO₂ nanocomposite material were synthesized using a (lab-scale) CHFS process, the basic design of which has been described at both lab-scale [43] and pilot plant scale (production capacity up to ca. 2 kg h⁻¹) [44]. Critical to the continuous production of nanoparticles in flow via the CHFS process is the patented (co-current) Confined Jet Mixer (CJM) [45] made from off-the-shelf SwagelokTM parts. The CJM, under these conditions, facilitates highly efficient (turbulent) mixing of a low-density supercritical water stream with a denser ambient temperature aqueous metal salt solution stream. In the CHFS process of the authors, three Primeroyal K diaphragm pumps (Milton Roy, Pont-Saint-Pierre, France, pressurized to 24.1 MPa) were used to supply the three process feeds; first, DI water (10 MΩ) was supplied by Pump 1 and heated in flow to above its critical point ($T_c = 374$ °C and $P_c = 22.1$ MPa) to a temperature of 450 °C using a custom-made in-line 7 kW electrical water heater. Pump 2 was used to supply the aqueous solution of metal salt(s) and Pump 3 supplied DI water. Feeds 2 and 3 were first combined in flow in a dead-volume Tee-piece at room temperature, before mixing with the superheated DI water feed (pumped from Pump 1) inside the CJM under highly turbulent conditions (Reynolds number of ca. 6000).

The metal salt precursors used were TiBALD [titanium(IV) bis(ammonium lactato)dihydroxide solution, 50 wt% in H₂O, Sigma-Aldrich, Steinheim, Germany], ammonium molybdate tetrahydrate (99.98 %, Sigma-Aldrich, Steinheim, Germany), and L-ascorbic acid (99 %, Sigma-Aldrich, Steinheim, Germany). Before use, an aqueous solution of the molybdenum salt was stirred vigorously for ten minutes with ascorbic acid to reduce Mo⁶⁺ to Mo⁴⁺, which was accompanied by a change in colour of the solution from yellow to dark blue.

For the synthesis of $\text{TiO}_2/\text{MoO}_2$ composite with a Ti:Mo atomic ratio of 1:4, Pump 2 was used to deliver a feed of 0.4 M $[(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}\cdot 4\text{H}_2\text{O}]$, 0.4 M $\text{C}_6\text{H}_8\text{O}_6$ and 0.1 M TiBALD. For the synthesis of MoO_2 , Pump 2 supplied a feed of 0.3 M $[(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}\cdot 4\text{H}_2\text{O}]$ and 0.3 M $\text{C}_6\text{H}_8\text{O}_6$.

The mixing of the aforementioned metal salt feeds with supercritical water (in the CJM) led to the rapid formation of nanoparticles in flow. After a residence time of ca. 5 s, a 1 m pipe-in-pipe counter-current cooler (heat exchanger) was used to cool the hot aqueous stream of nanoparticles down to ca. 40 °C. Thereafter, the cooled nanoparticle-laden aqueous slurry was recovered at the end of the CHFS process after passing through a back-pressure regulator valve. The particles were cleaned by dialysis in DI water for 48 h before being freeze-dried (Virtis Genesis 35XL) by first cooling the wet solids to -40 °C under vacuum of 13.3 Pa and subsequently heating to room temperature over 22 h.

2.2. Physical characterization

Powder X-ray diffraction (PXRD) data was collected in the 2θ range from 10 to 40 ° using $\text{Mo-K}\alpha$ radiation ($\lambda = 0.7107 \text{ \AA}$), with a step size of 0.5 °, and a step time of 20 s, on a STOE StadiP diffractometer.

High-resolution transmission electron microscopy (TEM) using a JEOL JEM 2100 – LaB_6 filament was used to determine size, interlayer spacing and particle morphology. A Gatan Orius digital camera was used for image capture of the samples that were pipetted on a 300-mesh copper film grid (Agar Scientific, Stansted, UK). Energy dispersive X-ray spectroscopy (EDS) was also performed using the JEOL JEM 2100 for elemental analysis of the samples.

The valence states of the metal ions in samples were determined using X-ray photoelectron spectroscopy (XPS) collected on a Thermo Scientific K-alpha™ spectrometer using $\text{Al-K}\alpha$ radiation equipped with a 128-channel position sensitive detector. High-resolution regional scans for molybdenum were conducted at 50 eV. Processing of the XPS data was performed using CasaXPS™ software (version 2.3.16) and by calibrating the spectra using the C 1s peak at 284.8 eV.

Brunauer-Emmett-Teller (BET) surface area measurements on as-prepared powders were carried out using liquid N_2 on a Micrometrics Tristar II. The samples were degassed at 150 °C (12 h) using Ar gas before measurements were undertaken.

Field emission scanning electron microscopy (FE-SEM) was carried out using a JEOL JSM-6700F microscope operating with an accelerating voltage of 5 kV, to study the surfaces of electrodes after cycling.

The tap densities of the nanomaterials were determined by measuring ca. 1.5 g of powder into a graduated cylinder and manually tapping it vertically on a benchtop 300 times.

2.3. Electrochemical characterization in half-cells

Anodes were prepared by mixing the CHFS-made MoO_2 active material with a polymeric binder (polyvinylidene fluoride, PVDF, PI-KEM, Staffordshire, UK) and a conductive carbon (Super P, Alfa Aesar, Heysham, UK) in a ratio of 80:10:10 wt.%. The PVDF was added as a pre-mixed 10

wt% solution of PVDF in N-methyl-2-pyrrolidone (NMP, Sigma Aldrich, St. Louis, USA). The solution was mixed manually with the active material and the conductive carbon and further NMP (ca. 2.5 mL) was added to yield a viscous slurry. The slurry was ball-milled at 800 rpm for 1 hour before being cast on 9 μm copper foil (PI-KEM, Staffordshire, UK) as the current collector. The electrode sheets were dried on a hotplate at ca. 150 $^{\circ}\text{C}$ for 20 minutes, until superficially dry and then left to continue drying overnight at room temperature. All electrodes were then dried overnight under vacuum at 40 $^{\circ}\text{C}$ before being introduced into an Ar-filled glovebox (H_2O and $\text{O}_2 < 5$ ppm) for cell assembly. The active mass loading of the anodes was in the range 1.8 to 2.0 mg cm^{-2} .

Half-cell tests were performed using CR2032 coin cells. Whatman GF/D glass microfiber filters (Buckinghamshire, UK) were used as the separator and drenched in an organic electrolyte (1 M LiPF_6 in 1:1 volume ratio ethylene carbonate/ethyl methyl carbonate, BASF, Ludwigshafen, Germany). For the half-cells, lithium metal foil (PI-KEM, Staffordshire, UK) was used as the counter electrode. Li-ion battery electrodes with $\text{TiO}_2/\text{MoO}_2$ or MoO_2 as the active component were tested using cyclic voltammetry in the potential window 0.1 to 3.0 V vs. Li/Li^+ , at scan rates in the range 0.1 to 100 mV s^{-1} . The half-cell galvanostatic charge/discharge cycling was carried out using an Arbin Instrument Model BT-2000 battery tester (Caltest Instruments Ltd, Guildford, UK), at room temperature. The tests were carried out in the potential range 0.1 to 3.0 V vs. Li/Li^+ , at specific currents in the range 0.1 to 15.0 A g^{-1} . Cyclic voltammograms (CV) for the half-cells were recorded in the potential window 0.1 to 3.0 V vs. Li/Li^+ , at scan rates in the range 0.1 to 100.0 mV s^{-1} .

Galvanostatic electrochemical impedance spectroscopy (EIS) was performed using a Gamry Interface 1000 instrument (Gamry Instruments, Pennsylvania, US). The AC current was set to 0.01 A rms. The frequency range was 100 kHz to 50 mHz.

Staircase potentiometric electrochemical impedance spectroscopy (SPEIS) was performed on Swagelok-type half-cells using a Bio-Logic VSP-300 potentiostat (Bio-Logic Science Instruments, Seyssinet-Pariset, France) in the potential window 0.1 to 3.0 V vs. Li/Li^+ with a potential of 0.01 V rms in the frequency range 100 kHz to 10 mHz. Each potential step was held until the measured current had relaxed to below 1 mA.

2.4. Electrochemical characterization in Li-ion hybrid electrochemical capacitors

Anodes, cut from the same sheet as those used for testing in Li-ion half-cells, were used in Li-ion hybrid electrochemical capacitors (Li-HECs), due to their excellent performance at high applied currents in Li-ion half-cells. Activated carbon (AC) electrodes were used as cathodes. The preparation of the AC electrodes has previously been described elsewhere [16]. In brief, they were prepared by mixing 87 wt% activated carbon active material (YP50F, Kuraray Chemical Co., Osaka, Japan) with 8 wt% of a binder (PVDF) and 5 wt% carbon black (SuperPTM) and casting on a Megtec reel-to-reel coater on aluminium foil.

Electrochemical tests for the Li-HECs were performed in two-electrode Swagelok-type cells that were assembled in an Ar-filled glovebox with levels of O_2 and $\text{H}_2\text{O} < 5$ ppm. Whatman GF/D glass microfiber filters (Buckinghamshire, UK), drenched in an organic electrolyte (1 M LiPF_6 in 1:1

volume ratio of ethylene carbonate/ethyl methyl carbonate, BASF, Ludwigshafen, Germany), were used as separators. The mass ratio between active material in anode and cathode was not optimized, and kept in line with previous reports at a mass ratio of ca 2:7 [16].

Cyclic charge/discharge measurements and CVs for the Li-HECs were performed on a Gamry Interface 1000 instrument (Gamry Instruments, Pennsylvania, US). Galvanostatic charge/discharge cycling was performed at current densities in the range of 2.0 to 20.0 mA cm⁻² (based on the geometric surface area of the electrodes), in the potential window of 1.0 to 3.0 V. This was equivalent to specific currents based on the mass of active materials in both electrodes of ca. 0.3 to 3.0 A g⁻¹. The CVs were performed at scan rates in the range 5 to 100 mV s⁻¹, in the potential window 1.0 to 3.0 V.

3. RESULTS AND DISCUSSION

Well-dispersed dark slurries of nanoparticles were obtained, which settled overnight (after the addition of ca. 50 g of NaCl per litre of dispersion). The supernatant was removed, and the black wet solids were dialysed in DI water. After dialysis and freeze-drying, both the nanoparticle samples were recovered as shiny black powders. Due to the high stability of the dispersions and small particle sizes, there were some losses during clean-up, which were higher for the pure MoO₂ sample. A yield of > 90% was recorded for the composite sample, which meant a production process rate of > 85 g per hour.

Powder XRD data for the nanoparticle MoO₂ revealed well-defined peaks (see Figure 1a) that showed similarities to the standard reference pattern for tugarinovite MoO₂ (JCPDS reference card no. 078-1073, space group P2_{1/c}). The major peaks for both samples corresponded to the (011), (-211) and (-311) peaks for MoO₂ (2θ = 11.9, 16.7 and 23.9 °, respectively). The XRD data for the TiO₂/MoO₂ composite additionally showed a shoulder associated with the peak at 2θ = 11.6 °, corresponding to the (101) peak of anatase TiO₂, as well as a peak at 2θ = 21.6 °, corresponding to the (200) peak of anatase. Application of the Scherrer equation to some of the major XRD peaks suggested crystallite sizes of ca. 16 nm for MoO₂ in the pure sample and ca. 11 nm for MoO₂ in the composite material. Crystallite size analysis on the deconvoluted shoulder of the peak for TiO₂ gave an estimated crystallite size of ca. 5 nm.

The valence states of titanium and molybdenum ions, both in the TiO₂/MoO₂ composite and pure MoO₂, were determined using high-resolution X-ray photoelectron spectroscopy (XPS). The Ti 2p level binding energies for the TiO₂/MoO₂ composite were at 459.1 and 465.0 eV for Ti 2p_{3/2} and Ti 2p_{1/2}, respectively. This gave a spin-orbit splitting of 5.9 eV that could be ascribed to the core level of Ti⁴⁺. A comparison of Ti2p peaks showed little difference between the Ti⁴⁺ species found in the composite compared to that in pure TiO₂ [16]. For Mo ions, three distinct peaks were observed at 229.6, 232.8 and 236.0 eV, which were ascribed to a mixture of Mo⁴⁺, Mo⁵⁺ and Mo⁶⁺ valence states in the samples (see b and c). This was most likely due to surface oxidation of Mo⁴⁺ in the Mo⁴⁺O₂²⁻ to a surface layer of molybdenum oxides, such as Mo₂O₅ and MoO₃, as has previously been observed elsewhere [46,47].

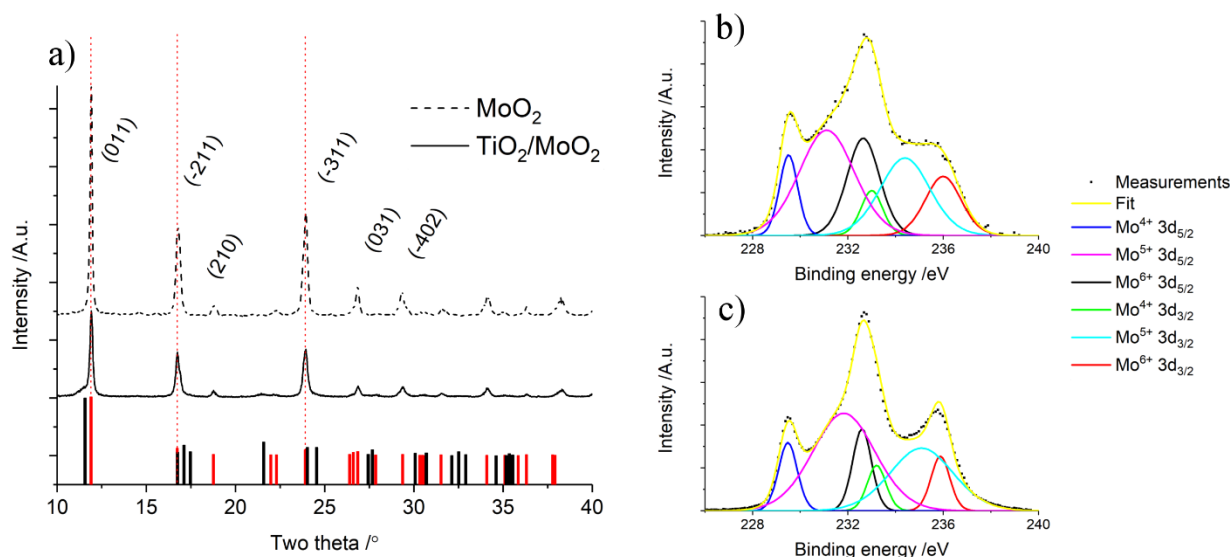

Figure 1. a) Powder X-ray diffraction (PXRD) patterns for both $\text{TiO}_2/\text{MoO}_2$ and MoO_2 with reference patterns for MoO_2 (tugarinovite, JCPDS card no. 078-1073) marked by red columns and TiO_2 (anatase, JCPDS card no. 071-1167) marked by black columns. High-resolution X-ray photoelectron spectroscopy (XPS) for Mo3d for both the composite b) $\text{TiO}_2/\text{MoO}_2$ and c) pure MoO_2 .

Semi-quantitative analysis of the XPS peak areas for the $\text{TiO}_2/\text{MoO}_2$ composite suggested an estimated elemental composition of ca. 60 at% titanium, which indicated a strongly enriched loading of TiO_2 on the surface. Hence, TiO_2 nanoparticles may have been concentrated on the surface of MoO_2 nanoparticles in the composite sample.

EDS analysis revealed an even distribution of titanium ions throughout the $\text{TiO}_2/\text{MoO}_2$ composite (see Figure 2a-d). This homogeneity was contrasted by the distribution of Mo ions, which did not appear to be as homogeneously distributed. Parts of the sample showed high molybdenum ion concentration, some equal concentrations of Ti and Mo ions and some with no molybdenum ions at all. This suggested that the elements had formed separate phases, due to a combination of either very different rates of hydrolysis or simply low solid solution solubility. Elemental analysis of several large agglomerates of composite material using EDS showed, on average, good agreement with the original Ti:Mo molar ratio used in the synthesis, suggesting a value of 21 ± 2 at% titanium.

Transmission electron microscopy revealed small spherical particles for both samples (Figure 3a and 3c). TEM images suggested an average particle size (150 particles counted) of 18.9 ± 6.2 nm for MoO_2 compared to 9.1 ± 5.9 nm for the $\text{TiO}_2/\text{MoO}_2$ composite (see Figure 2e and 2f). The interlayer spacings for both samples were determined by analysis of TEM image lattice fringes, as shown in Figure 3b and 3d. Two different interlayer spacings of 0.24 and 0.34 nm were observed for both samples that corresponded to the (-211) and (011) interlayer spacings, respectively, of monoclinic MoO_2 [48].

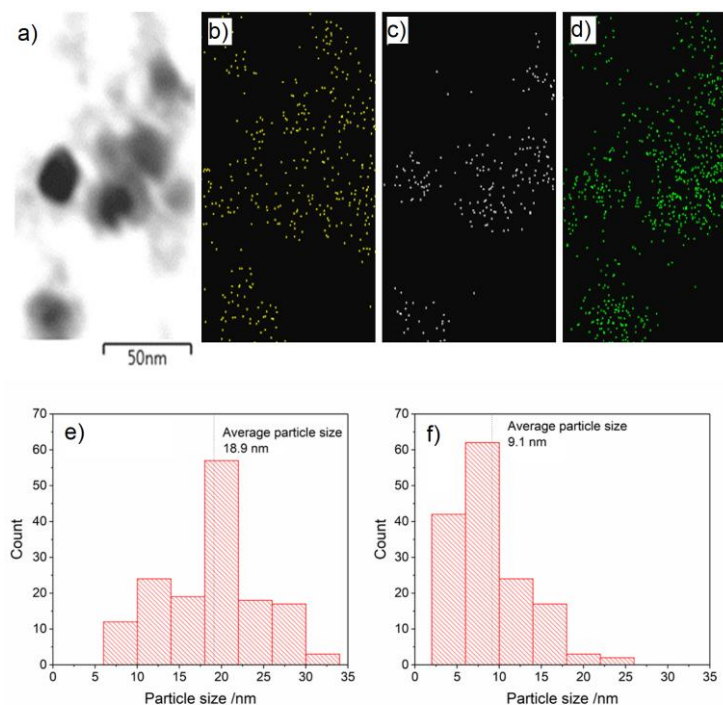

Figure 2. a) Scanning transition electron microscopy (STEM) dark-field image showing the $\text{TiO}_2/\text{MoO}_2$ composite and energy-dispersive X-ray spectroscopy (EDS) maps for b) Ti (yellow), c) Mo (grey), and O (green). Histograms showing the particle sizes of 150 particles for both e) the pure MoO_2 sample and f) the $\text{TiO}_2/\text{MoO}_2$ composite.

Figure 3. Transmission electron microscopy (TEM) images showing the a) $\text{TiO}_2/\text{MoO}_2$ composite and the interlayer spacing of b) the $\text{TiO}_2/\text{MoO}_2$ composite. TEM image showing the particle size and morphology of c) the pure MoO_2 particles as well as d) an image showing the interlayer spacings for pure MoO_2 .

The BET surface area values for the pure MoO₂ and TiO₂/MoO₂ samples were ca. 21 and 105 m² g⁻¹, respectively. Pure TiO₂ synthesised via CHFS has previously been reported to possess a specific surface area of ca. 280 m² g⁻¹ [49], therefore, even assuming separate formation of 20 mol% TiO₂ and 80 mol% MoO₂ particles (equal to 14 wt% TiO₂ and 86 wt% MoO₂), the surface area of MoO₂ particles in the composite was increased by the presence of Ti salt.

The tap density of the as-synthesised pure MoO₂ was 0.92 g cm⁻³, whereas that of the TiO₂/MoO₂ composite was 1.54 g cm⁻³. This significant increase in tap density was possibly a result of the decreased particle size and better packing of the composite sample.

The results from potentiodynamic tests for the composite nanomaterial and pure MoO₂ are shown in Figure 4a and 4b, respectively (at scan rates of 0.1, 0.2, 0.5 and 1.0 mV s⁻¹). Plots for the composite nanomaterial at 0.1 mV s⁻¹ showed three distinct anodic peaks (Li⁺ extraction) at ca. 1.4, 1.7 and 2.1 V vs. Li/Li⁺, two major cathodic (Li⁺ insertion) peaks at 1.25 and 1.5 V vs. Li/Li⁺, and one minor peak at 1.8 V vs. Li/Li⁺. The two oxidation peaks at 1.4 and 1.7 V vs. Li/Li⁺ can be ascribed to the phase transitions from monoclinic to orthorhombic and back to monoclinic phase, as Li⁺ was extracted from the MoO₂ phase, as previously described in the literature [19,20]. The reactions of MoO₂ (in the composite or the pure material) in the potential range 1.0 to 3.0 V vs. Li/Li⁺ can therefore be described by Equation (1):

Cycling of MoO₂ (in the composite or the pure material) to lower potentials such as 0.1 V vs. Li/Li⁺ subsequently resulted in the partial conversion reaction of the fully lithiated Li_{0.98}MoO₂ to molybdenum metal and lithium oxide, as per Equation (2) [27,38,50]:

In the cyclic voltammogram of the composite materials, the additional extraction and insertion peaks at 2.1 V and 1.8 V vs. Li/Li⁺, respectively, was ascribed to the Ti³⁺/Ti⁴⁺ transition in TiO₂ [15,16]. As the scan rate increased, the separation between anodic and cathodic peaks increased due to polarization of the electrodes. At a scan rate of 1 mV s⁻¹, the third oxidation peak for the Ti³⁺/Ti⁴⁺ transition almost disappeared, whilst the two extraction peaks for MoO₂ were still very distinct.

The half-cells made using pure MoO₂ as the active material showed only the two Li-ion extraction peaks for MoO₂. These were at similar potentials to those observed for the composite sample, at ca. 1.4 and 1.7 V vs. Li/Li⁺ (at a scan rate of 0.1 mV s⁻¹). An increase in scan rate, however, resulted in a much smaller increase in current for the pure MoO₂ sample, and the peaks became less distinct. This indicated more sluggish Li-ion diffusion at high rates for this sample compared to the nanocomposite. This was confirmed by increased capacity retention for the composite sample at higher scan rates (see Figure 4c).

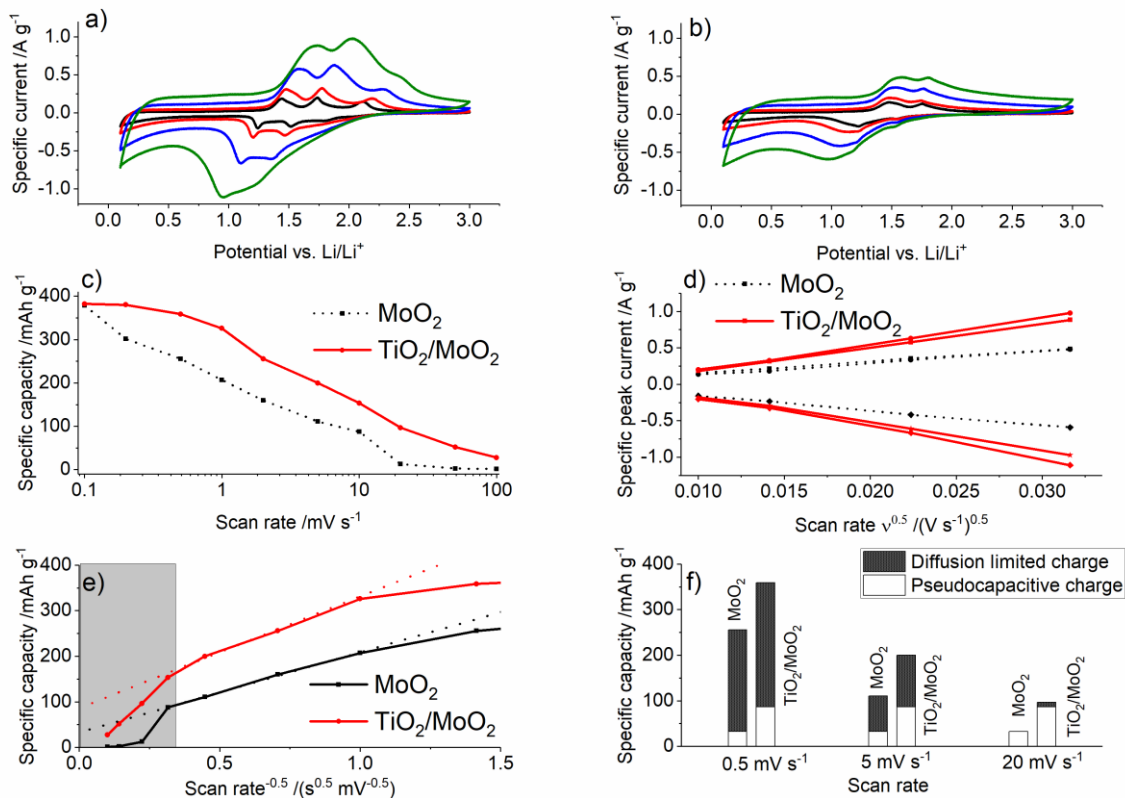

Figure 4. Cyclic voltammograms for a) $\text{TiO}_2/\text{MoO}_2$ composite and b) MoO_2 at 0.1, 0.2, 0.5 and 1.0 mV s^{-1} in black, red, blue and green, respectively. c) Plots of specific capacities over scan rate for both. d) The relationship between specific peak currents and scan rate. e) Plots of specific capacity vs. the reciprocal of the square root of the scan rate (with high scan rate region in grey excluded from analysis) and f) proportion of pseudocapacitive charge storage for both the composite and pure MoO_2 at scan rates of 0.5, 5 and 20 mV s^{-1} .

The relationship between specific peak current and scan rate for the intercalation peaks of MoO_2 was plotted in Figure 4d. Both anodic and cathodic peak currents were higher at each scan rate for the composite sample, compared to pure MoO_2 . The Randles-Sevcik equation [51–53] (Equation 3) was used to calculate the apparent diffusion coefficients.

$$I_p = 2.69 \times 10^5 n^{\frac{3}{2}} A D^{\frac{1}{2}} C v^{\frac{1}{2}} \quad (3)$$

In Equation 3, the peak current (I_p) is related to the number of electrons involved in the intercalation (n), the surface area of the electrode (A), the concentration of Li^+ (C), the scan rate (v) and the diffusion coefficient (D).

The specific diffusion coefficients for the pure MoO_2 sample were ca. 1.0×10^{-9} (anodic) and $1.3 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1} \text{ g}^{-1}$ (cathodic), whereas the diffusion coefficients for the composite $\text{TiO}_2/\text{MoO}_2$ sample were significantly higher (ca. 2.8×10^{-9} and $3.0 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1} \text{ g}^{-1}$ for anodic and cathodic redox processes, respectively). The contributions of both near-surface (fast Faradaic and minor double layer charge storage) processes and intercalation to the specific current were estimated using Equations 4, 5 and 6 [9,54,55].

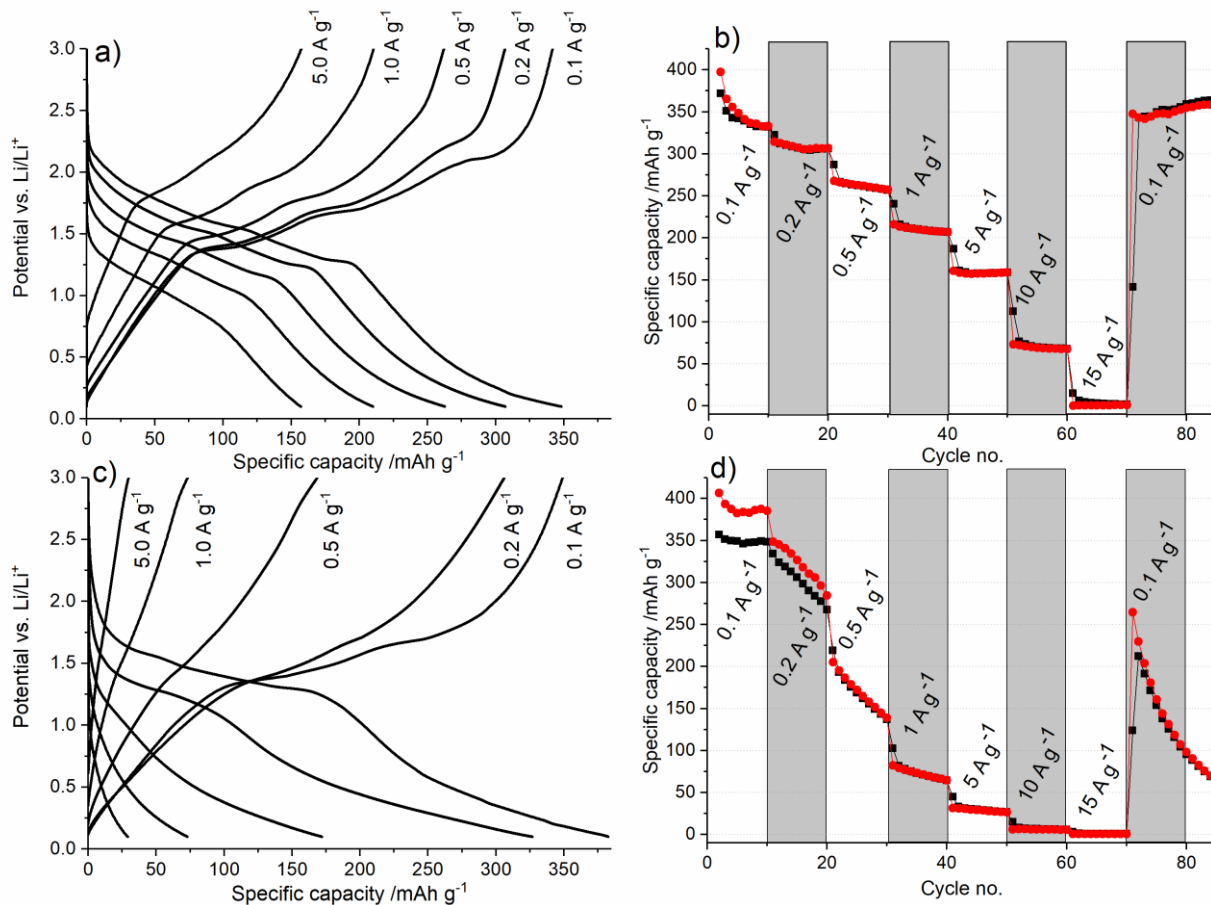

Figure 5. Charge/discharge curves for the 5th cycle for a) TiO₂/MoO₂ and c) pure MoO₂ at specific currents of 0.1, 0.2, 0.5, 1, and 5 A g⁻¹; as well as C-rate cycling data for b) TiO₂/MoO₂ and d) pure MoO₂, with both charge (red) and discharge (black) capacities shown.

The total current q_T can be expressed by Equation 4:

$$q_T = q_s + q_d \quad (4)$$

Where q_s is the charge related to fast pseudocapacitive charge storage and q_d the charge due to slower diffusion-limited processes.

The pseudocapacitive contribution to charge storage (PCS) can therefore be calculated using Equation (5), and because the diffusion-controlled behaviour is linearly related to $v^{-0.5}$, Equation 4 can be rewritten as Equation 6:

$$PCS = q_s/q_T \quad (5)$$

$$q_T = q_s + cv^{-0.5} \quad (6)$$

The specific capacity was plotted versus reciprocal square root of the scan rate ($v^{-0.5}$) in Figure 4e. The pseudocapacitive contributions to charge storage were calculated to be ca. 24 % at 0.5 mV s⁻¹ for the composite sample, but only ca. 13 % for the pure MoO₂ (see Figure 4f). At a higher scan rate of 5 mV s⁻¹ the PCS contributions were ca. 43 and 30 % for TiO₂/MoO₂ and pure MoO₂, respectively. Finally, at 20 mV s⁻¹, pseudocapacitive charge storage contributions were nearly 100 % for both samples; calculated pseudocapacitive charge stored at a theoretical, infinitely fast scan rate was 311 C g⁻¹ for TiO₂/MoO₂, but only 119 C g⁻¹ for MoO₂.

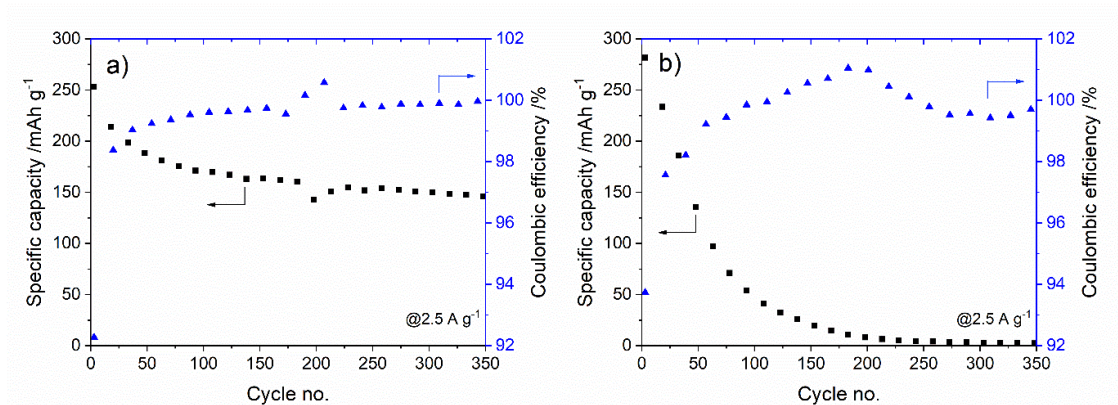

Figure 6. Specific capacities (black squares) and Coulombic efficiencies (blue triangles) for Li-ion half-cells of electrodes made from a) nanocomposite TiO₂/MoO₂ and b) pure MoO₂ nanoparticles; both at a constant specific current of 2.5 A g⁻¹.

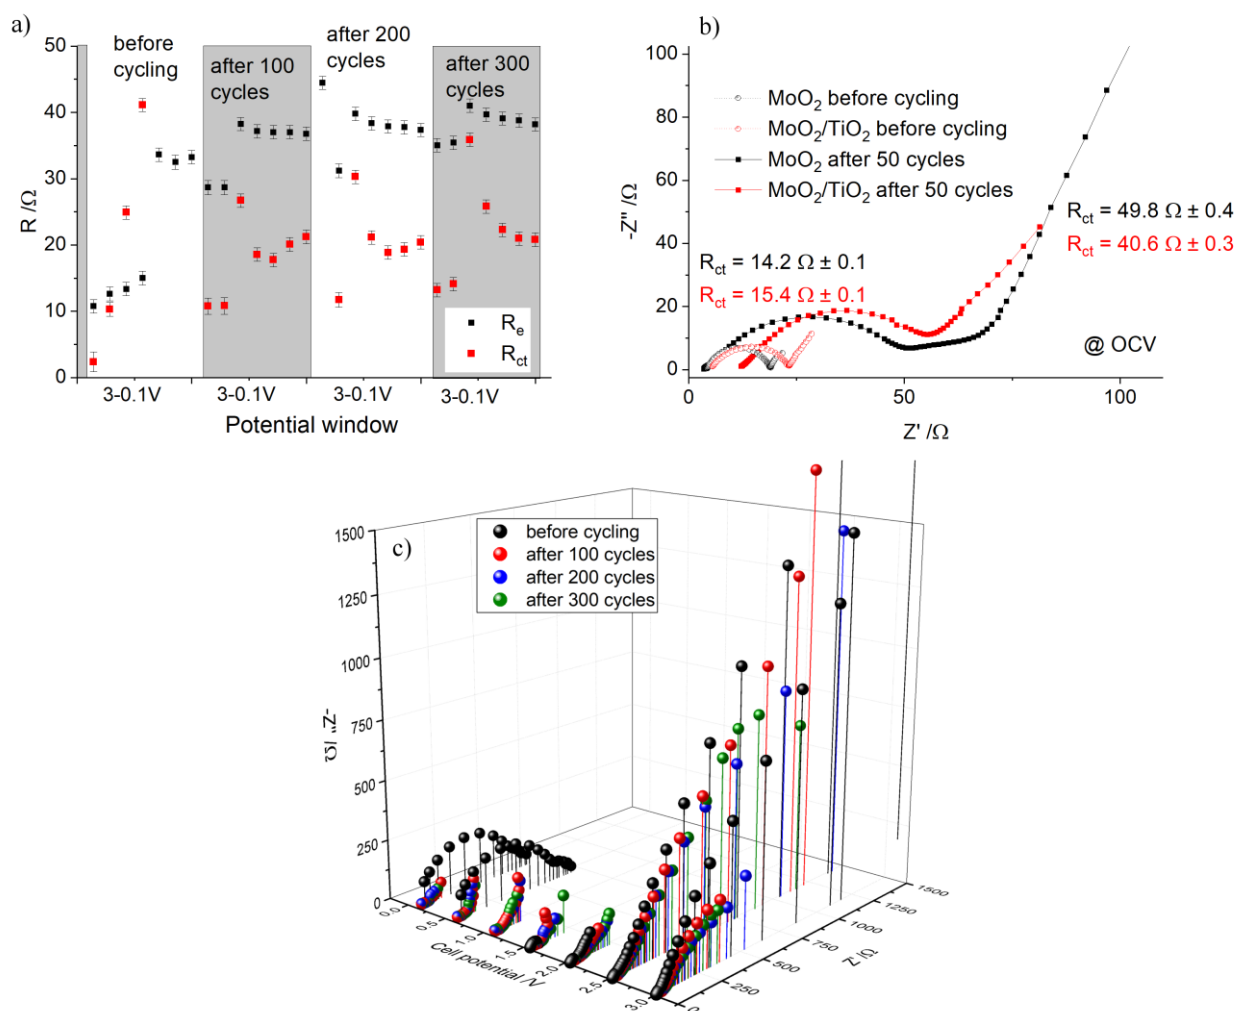

Figure 7. a) Development of the electronic resistance (R_e) and charge transfer resistance (R_{ct}) during staircase potentiodynamic electrochemical impedance spectroscopy (SPEIS) in the potential range 3.0 to 0.1 V vs. Li/Li⁺, before and after cycling. b) EIS of half-cells is shown in electrodes using MoO₂ (black) and the TiO₂/MoO₂ composite (red) as the active material. The data is shown for both before cycling (spheres) and after cycling (squares). c) Nyquist plots at various potentials before cycling and after 100, 200 and 300 cycles.

These values were comparable to those previously reported in the literature for nanosized MoO_2 (values reported were 300 C g^{-1} at 10 mV s^{-1}) [12]. Herein, the larger contribution of pseudocapacitive charge storage in the composite sample was attributed to the small size of the MoO_2 particles in the composite (versus the pure MoO_2 material), which facilitated rapid near-surface charge transfer processes [56].

These findings were supported by the results of galvanostatic charge/discharge measurements (see Figure 5a and 5c) at specific currents of 0.1, 0.2, 0.5, 1, 5, 10 and 15 A g^{-1} , in the potential window of 0.1 to 3.0 V vs. Li/Li^+ . The charge/discharge curves for half-cells containing $\text{TiO}_2/\text{MoO}_2$ electrodes at lower currents (e.g. 0.1 A g^{-1}) showed three separate plateaus. The two plateaus, at lower potentials vs. Li/Li^+ , corresponded to a phase transformation from monoclinic $\text{Li}_{0.98}\text{MoO}_2$ to orthorhombic Li_xMoO_2 ($0.45 < x < 0.78$) and back to monoclinic MoO_2 [19], as observed from peaks in the cyclic voltammograms.

The plateau at ca 2.0 V vs. Li/Li^+ was due to lithium extraction from the anatase lattice of the TiO_2 [14]. This assignment was supported by the observation that no corresponding plateau was found in the charge/discharge profile for the half-cells with anodes made of pure MoO_2 .

Current rate testing revealed similar initial specific discharge capacities for both samples at low applied currents (ca. 350 mAh g^{-1} at 0.1 A g^{-1} after 10 cycles). However, there were significant differences at higher specific currents (see Figure 5b and 5d). The half-cells containing the $\text{TiO}_2/\text{MoO}_2$ composite showed superior capacity retention and rate behaviour (as well as higher Coulombic efficiencies) in the first twenty cycles at lower applied currents. An increase in the applied specific current to 0.2 A g^{-1} led to a significant reduction in specific capacity for the pure MoO_2 electrodes and noticeable reduction in cycle life, with a loss of 25 % in capacity after 10 cycles. In comparison, at a specific current of 1 A g^{-1} , the $\text{TiO}_2/\text{MoO}_2$ composite electrodes showed a stable specific discharge capacity of ca. 225 mAh g^{-1} . Under similar conditions, the cell with pure MoO_2 showed a steadily decreasing specific discharge capacity $< 100 \text{ mAh g}^{-1}$. Even at specific currents of 5 and 10 A g^{-1} , The $\text{TiO}_2/\text{MoO}_2$ composite half-cells still delivered stable and high specific discharge capacities of ca. 160 and 70 mAh g^{-1} , respectively. This meant that a specific capacity of 160 mAh g^{-1} could be stored and discharged within less than 2 minutes.

When the specific current was subsequently returned to 0.1 A g^{-1} after 70 cycles at a range of specific currents (up to 15 A g^{-1}), the specific capacity of $\text{TiO}_2/\text{MoO}_2$ recovered to ca. 350 mAh g^{-1} and remained stable. In contrast, the pure MoO_2 cell was unstable, and after recovering to a specific capacity of ca. 210 mAh g^{-1} , dropped down to ca. 100 mAh g^{-1} after another 10 cycles at 0.1 A g^{-1} . The improved capacity and cycling stability for the $\text{TiO}_2/\text{MoO}_2$ electrode was attributed to the diluting and/or stabilising effect of TiO_2 particles (which underwent minimal volume changes upon cycling) on the normally relatively unstable MoO_2 conversion material when cycled below 1.0 V vs. Li/Li^+ . This was in line with cycling stability tests at 2.5 A g^{-1} (see Figure 6). The $\text{TiO}_2/\text{MoO}_2$ composite retained a specific capacity of ca. 150 mAh g^{-1} after 350 cycles, however, the pure MoO_2 cell could not retain any capacity after 200 cycles (and was $< 100 \text{ mAh g}^{-1}$ after 70 cycles). By comparison, pure TiO_2 synthesised via CHFS cycled in the same potential window showed significantly worse performance, with maximum specific capacities of only ca. 225 and 120 mAh g^{-1} at specific currents of 0.1 and 1 A g^{-1} , respectively [57].

TiO₂ has previously been used in composite electrodes to enhance the cycling performance and stability of Li-ion cells containing alloying materials such as sulphur and MoS₂ [31,58,59]. Herein, the improved charge storage at high rates can be explained by the smaller particle size and higher surface area of the MoO₂ phase in the TiO₂/MoO₂ composite particles [56,60], which led to higher pseudocapacitive contributions and better apparent lithium-ion diffusion at high applied currents.

Staircase Potentio Electrochemical Impedance Spectroscopy (SPEIS) of half-cells using anodes made from the TiO₂/MoO₂ composite revealed that at a potential of 3.0 V vs. Li/Li⁺ (fully discharged state), the Nyquist profile changed significantly after cycling. Both charge transfer resistance and solution resistance were largely consistent after cycling, revealing similar Nyquist plots after 100, 200 and 300 cycles. At 2.0 V vs. Li/Li⁺, the Nyquist plots, after 100, 200, and 300 cycles, remained consistent but were significantly different to the Nyquist plot before cycling. Due to electrolyte decomposition, the solution resistance (R_e) was significantly higher after cycling than it was before, both at 3.0 and 2.0 V vs. Li/Li⁺.

Figure 8. Scanning electron microscopy (SEM) images of electrodes (after cycling for 40 cycles) from cells made using (a, c) a TiO₂/MoO₂ composite active material and (b, d) a pure MoO₂ active material. Charge/discharge curves (40 cycles at 0.2 A g⁻¹) for the half-cells containing (e) the TiO₂/MoO₂ composite and (f) pure MoO₂.

Figure 9. a) and b) Constant charge/discharge profiles for TiO₂/MoO₂//Activated carbon Li-ion hybrid electrochemical capacitors as well as c) cyclic voltammetry and d) specific capacitance of the whole cell at various scan rates.

The maximum charge transfer resistances (R_{ct}) were observed at a potential of 2.0 V vs. Li/Li⁺ for all measurements after cycling and increased from 27 to 36 Ω after cycling for 100 and 300 cycles, respectively. For impedance measurements taken in the potential window of 1.5 to 0.1 V vs. Li/Li⁺, charge transfer and solution resistances did not differ significantly with different potentials and cycles. The general trend in charge transfer resistance was to increase as the cut-off potential of 0.1 V vs. Li/Li⁺ was approached (see Figure 7a). The resistance due to solid electrolyte interphase formation R_{SEI} showed no clear pattern and remained in the range 11 to 20 Ω after 100, 200 and 300 cycles.

At open circuit voltage, the Nyquist plots (see Figure 7b) suggested that the pure MoO₂ sample had lower charge transfer and lower total impedance before cycling, compared to the TiO₂/MoO₂ composite; this was expected considering the near-metallic conductivity of crystalline pure MoO₂ [20] compared to the relatively poor conductivity of TiO₂ [14] and the additional phase boundaries in the composite material. However, after 40 cycles at a current rate of 0.1 A g⁻¹, the composite electrodes showed a smaller increase in charge transfer resistance. The Nyquist plots for pure MoO₂ electrodes also showed clear evidence for the presence of a second phase at OCV after cycling with an indented semicircle in the Nyquist plot in the range 50 to 70 Ω that was not observed in the corresponding plot for the composite electrode. The previously described stability of the composite electrode was also observed via SPEIS (see Figure 7c), with very little difference between half-cells cycled for 100, 200 or 300 cycles. For the composite electrodes cycled at a current rate of 0.5 A g⁻¹, the capacity losses

were ca. 22, 13 and 8 % of the original capacity in the ranges 0 to 100, 100 to 200 and 200 to 300 cycles, respectively.

To explain the significantly worsening performance of the half-cells containing the pure MoO_2 electrodes, post-mortem scanning electron microscopy (SEM) was carried out. The cycled electrodes of each material showed micro-cracks, which were relatively minor for the $\text{TiO}_2/\text{MoO}_2$ electrode (see Figure 8a and c), but much larger and connected for the pure MoO_2 electrode (see Figure 8b and d). The expansion/shrinking during lithiation and delithiation, especially during the conversion reaction, may have been responsible for cracking for each set of materials [24] and the electrode itself [61]. Due to its chemical and structural stability, TiO_2 has also been used to improve the stability of other active materials; for example, in $\text{TiO}_2@\text{Fe}_2\text{O}_3$ arrays [62], $\text{Fe}_3\text{O}_4@\text{TiO}_2$ clusters [30], and as previously mentioned a $\text{MoS}_2/\text{TiO}_2$ composite [59].

Because of its superior performance at high specific currents, the $\text{TiO}_2/\text{MoO}_2$ composite was identified as a potential anode material for a Li-ion hybrid electrochemical capacitor (Li-HEC). The cycling was limited to a potential window of 1.0 to 3.0 V to avoid lithium plating and the conversion reaction of the anode (to improve cycle life). Cyclic voltammograms revealed plots similar to those previously reported for similar Li-HECs [16,63]. Visible peaks for redox reactions were fairly indistinct at the slowest scan rate of 5 mV s^{-1} , indicating good capacitor behaviour [64]. With increasing scan rate, the plots became increasingly featureless and broader (see Figure 9c). Interestingly, the behaviour was as would be expected for a typical Li-HEC, i.e. combining both capacitor-like and battery-like charge storage mechanisms [64–66]. During charging, fast Faradaic reactions of lithium cations with the anode, and hexafluorophosphate anion absorption onto the active carbon cathode, were expected. During discharging, PF_6^- desorption and Li^+ extraction from the active material in the anode were expected [9,10,67].

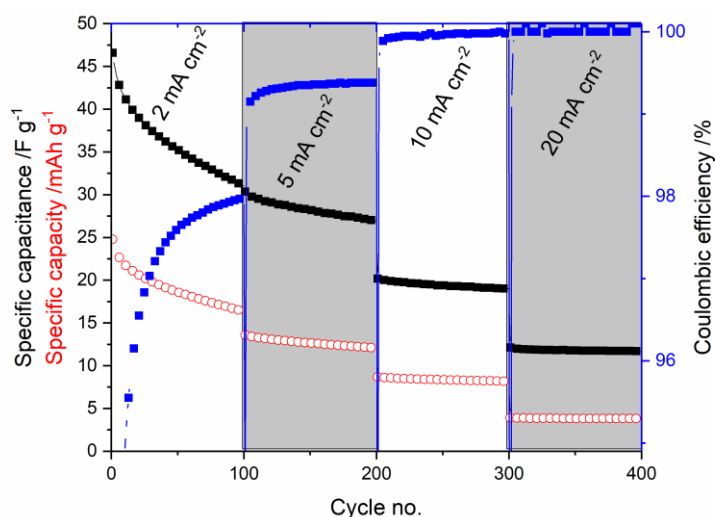

Figure 10. Cyclic charge/discharge measurements of $\text{TiO}_2/\text{MoO}_2//\text{AC}$ Li-ion hybrid electrochemical capacitor at varying current densities.

The specific capacitance of the Li-HEC was calculated using Equation (7):

$$C_{\text{cell}} = Q/(\Delta V m) \quad (7)$$

Where Q was the charge (C), ΔV was the voltage change (V) and m was the mass of active material in both the anode and cathode (g). The TiO₂/MoO₂//AC Li-HEC showed specific capacitances of 44, 36, 33, 26, and 18 F g⁻¹ at scan rates of 5, 10, 20, 50, and 100 mV s⁻¹, respectively (see Figure 9d).

These values were in good agreement with the results from the cyclic charge/discharge measurements, which were analysed using Equations (8) and (9):

$$C_{\text{cell}} = (I t) / (\Delta V m) \quad (8)$$

$$\Delta V = E_{\text{max}} - E_{\text{min}} \quad (9)$$

Where I was the charge current (A), t was the discharge time (s), ΔV was the potential window (V), and m was the mass of active material in both the anode and cathode (g). E_{max} and E_{min} were the potentials at the beginning and at the end of the discharge step.

At current densities of 2, 5, 10, and 20 mA cm⁻², which were equivalent to specific currents of ca. 0.3, 0.75, 1.5 and 3.0 A g⁻¹ (based on the mass of active materials in both cathode and anode), respectively, the TiO₂/MoO₂//AC Li-HEC showed specific capacitances of 40, 26, 19, and 12 F g⁻¹ (equivalent to specific capacities of 22, 13, 8 and 4 mAh g⁻¹), respectively. The charge/discharge curves had a nearly triangular shape, consistent with the expectations for a Li-HEC and indicative of good capacitive behaviour (see Figure 9a and 9b) [64]. The capacities and capacitances of the TiO₂/MoO₂//AC Li-HEC is shown in Figure 10.

After three formation cycles at 1 mV s⁻¹, the Li-HEC using the composite as active material showed good capacity retention (65 %) over 3000 cycles at 5 mA cm⁻².

To better compare these results to similar systems in the literature, power and energy densities were calculated using Equations (10), (11) and (12) to further investigate the performance:

$$P = \Delta V (I/m) \quad (10)$$

$$E = P (t/3600) \quad (11)$$

$$\Delta V = (E_{\text{max}} + E_{\text{min}}) / 2 \quad (12)$$

Where E_{max} and E_{min} were the potentials at the beginning and the end of the discharge, therefore, ΔV gave the average potential (V), I was the current (A), m was the mass of the active materials in both anode and cathode (kg) and t was the discharge time (s).

The TiO₂/MoO₂//AC Li-HEC showed high energy density of 44 Wh kg⁻¹ at a moderate power density of 600 W kg⁻¹ and even at a power density of 2700 W kg⁻¹, it demonstrated an energy density of 15 Wh kg⁻¹. To demonstrate the performance of the devices, a Ragone graph was plotted in Figure 11, showing the data herein, alongside similar systems in the literature employing different anode materials, including TiO₂-reduced graphene oxide [63,68], anatase TiO₂ [63], Li₄Ti₅O₁₂ [68,69], TiO₂-B [70], TiO₂(B) [71], LiCrTiO₄ [72], Ti₉O₁₇ [73], and TiO₂ microspheres wrapped with graphene nanosheets (against a graphene nanosheet positive electrode) [74].

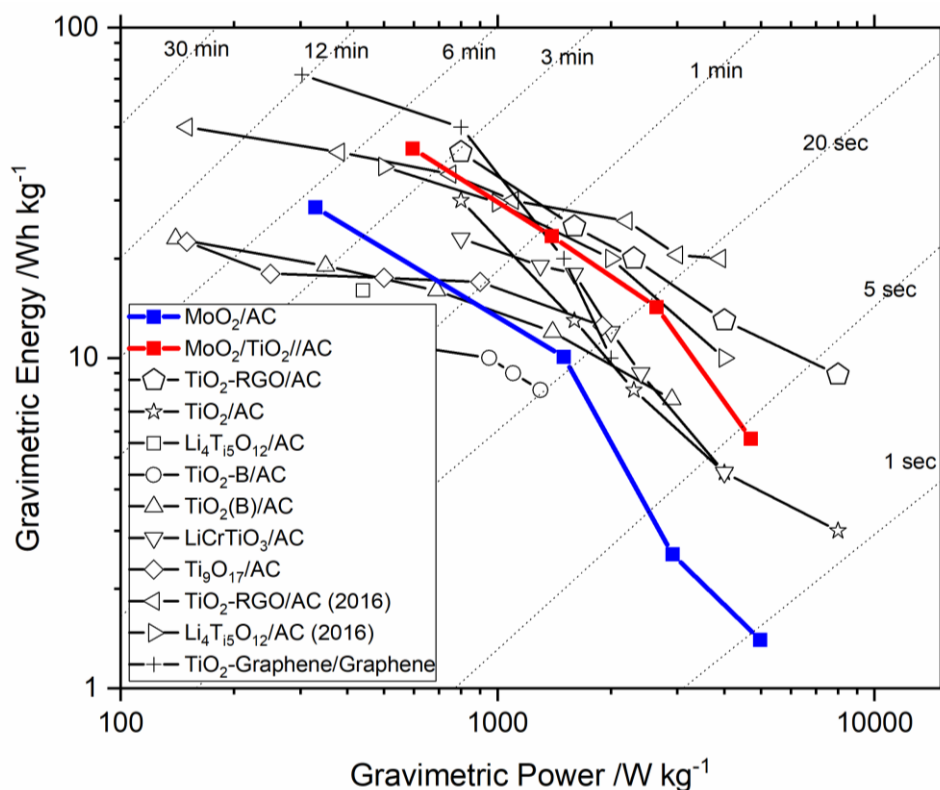

Figure 11. Ragone plot of the results herein compared to devices using anodes such as TiO₂-Reduced Graphene oxide and anatase TiO₂ [63], Li₄Ti₅O₁₂ [69], TiO₂-B [70], TiO₂(B) [71], LiCrTiO₄ [72], Ti₉O₁₇ [73], TiO₂-Reduced Graphene oxide (2016) and Li₄Ti₅O₁₂ (2016) [68], TiO₂ microspheres wrapped with graphene nanosheets versus a graphene nanosheet positive electrode [74].

4. CONCLUSIONS

Nano-sized pure MoO₂ and a TiO₂/MoO₂ nanocomposite were separately synthesised using a one-step continuous hydrothermal flow synthesis method. Adding 20 mol% titanium salt in the precursor feed containing the Mo salt significantly improved reaction yield and reduced the size of MoO₂ particles, which resulted in a fivefold increase in surface area.

The presence of TiO₂ and small size of MoO₂ in the composite material significantly improved the electrode cycle life in Li-ion half-cells. The reduced average particle size increased lithium-ion diffusion and facilitated larger pseudocapacitive contributions to charge storage, which led to better high-rate performance compared to pure MoO₂. The improved cycling stability of the composite was believed to be a result of TiO₂ acting as a buffer (to excessive volume changes) and an anchor for Mo and MoO₂ species that were formed/reformed during cycling.

The composite material showed significantly superior high-rate performance with a specific discharge capacity of 150 mAh g⁻¹ at 5 A g⁻¹ and better cycle life than the pure MoO₂ anodes. The composite half-cells also showed higher specific capacities than cells made from pure TiO₂ electrodes reported in the literature and cycled in the same potential window. A Li-HEC, using TiO₂/MoO₂ as

active anode material and an activated carbon cathode, showed high energy densities of 44 Wh kg⁻¹ and 15 Wh kg⁻¹ at power densities of 600 W kg⁻¹ and 2700 W kg⁻¹, respectively.

ACKNOWLEDGEMENTS

The EPSRC are thanked for funding the Centre for Doctoral Training in Molecular Modelling & Materials Science (UCL, UK) and JAIST (Kanazawa, Japan) are thanked for supporting a studentship for DB. DJLB and PRS thank EPSRC for support of the ELEVATE (ELEctrochemical Vehicle Advanced TEchnology) low carbon vehicles project (EPSRC Ref. EP/M009394/1). JAD and CLS thank the JUICED Energy Hub for support (EPSRC Ref. EP/R023662/1).
