ABSTRACT

Inductive charging, a form of wireless charging, uses an electromagnetic field to transfer energy between two objects. This emerging technology offers an alternative solution to users having to physically plug in their electric vehicle (EV) to charge. Whilst manufacturers claim inductive charging technology is market ready, the efficiency of transfer of electrical energy is highly reliant on the accurate alignment of the coils involved. Therefore understanding the issue of parking misalignment and driver behaviour is an important human factors question, and the focus of this paper. Two studies were conducted, one a retrospective analysis of 100 pre-parked vehicles, the second a dynamic study where 10 participants parked an EV aiming to align with a charging pad with no bay markings as guidance. Results from both studies suggest that drivers are more accurate at parking laterally than in the longitudinal direction, with a mean lateral distance from the centre of the bay being 12.12 and 9.57 cm (retrospective and dynamic studies respectively) compared to longitudinally 23.73 and 73.48 cm. With current inductive charging systems having typical tolerances of approximately ±10 cm from their centre point, this study has shown that only 5% of vehicles in both studies would be aligned sufficiently accurately to allow efficient transfer of electrical energy through induction.

1. Introduction

Research and innovation into electric and alternatively fuelled vehicles – which includes pure Battery Electric Vehicles (BEV), Hybrid Electric Vehicles (HEV), Plug-in Hybrid Electric Vehicles (PHEV), or fuel cell vehicles (e.g. hydrogen) – is continuing at pace as they are viewed as a sustainable way to reduce both the dependency on fossil fuels and carbon output. The number, or available range, of 'electric miles' can be increased by storing energy in batteries located within the vehicle in order to power the drivetrain. When this store is depleted the batteries need to be recharged. This is typically done by plugging in a wired, or conductive, cabled system which is connected to the electricity grid. An emerging technology to support green driving is inductive charging.

Inductive, or wireless, charging uses an electromagnetic field to transfer energy between two objects, and offers an attractive alternative to the users having to physically plug in their EV or PHEV to charge the batteries. To initiate charging the user simply parks over a transmitting inductive coil which is embedded in the ground, and the receiving coil located on the vehicle automatically detects this and charging begins. Whilst inductive charging technology is market ready, the efficiency
of transfer of electrical energy is highly reliant on accurate alignment of the coils involved. He and colleagues envision that high-power, high-efficiency wireless power transfer technologies will be mature in the ‘near-future’ (He et al., 2013).

The key challenge in an automotive application is to transfer power over an air gap at an acceptable level of efficiency whilst meeting any legislative requirements, such as ensuring safety levels are met with respect to electromagnetic fields (ICNIRP, 2010; IEEE, 1992). A possible solution is resonant inductive coupling. This is the near-field (or short distance) wireless transmission of electrical energy between two coils that are highly resonant (or oscillate) at the same frequency. The efficiency of the energy transfer is a function of the frequency and alignment of the coils. Misalignment can occur across the vertical distance of the air gap, as well as lateral, longitudinal and angular misalignment. The efficiency of energy transfer generally drops rapidly once the misalignment reaches approximately 15–20 cm (Stanton, 2014). As a result, the control system will cut off the power, or the transfer will not commence when the efficiency is below 80%. However, an optimised system with perfect alignment of the two coils can result in transfer efficiencies of over 95%, which is comparable with wired charging.

Fig. 1 shows a typical wireless charging system. The power drawn from the supply is first rectified (or converted) through an AC/DC converter before being transformed to a high frequency (kHz) resonant signal by the inverter in the transmission pad installed on the ground. This energy is transferred across the air gap to the receiving pad on the vehicle through magnetic coils. At the receiving end, it is once again rectified to charge the battery in the vehicle. Development in coil design (i.e. multiple coils, field shaping, etc.) may result in marginal improvements in the physical efficiency bandwidth; however, the weak link in the chain is the driver and how accurately they can park, or drive over the coil to maximize energy transfer efficiencies.

Inductive power transfer (IPT; also known as wireless power transfer (WPT)) as a concept has been around for almost 200 years with its roots in both Ampère’s (1826) and Faraday’s (1831) Laws. In the 1890’s Nikola Tesla demonstrated how wireless power transfer can be used to illuminate incandescent lamps in New York. From these promising beginnings the technology largely remained untapped until recent years when in 2007 a team of researchers at MIT again demonstrated transmission of 60 W across a 2.5 m air gap to illuminate a light bulb. Concurrent development was being conducted by, amongst others, researchers at the University of Auckland who were investigating the wireless transfer of higher power ratings suitable for powering vehicles or changing plug-in vehicles.

In the UK the Society of Motor Manufacturers and Traders (SMMT) report that 9151 vehicles eligible for the UK Governments ‘Plug-in car grant’ – which offers a subsidy of up to £5000 off the purchase price of a plug-in vehicles (i.e. either BEV or PHEV) – have been purchased since the scheme began in January 2011 until April 2014. This equates to only 0.13% of new vehicle registration during this same time. Whilst this landscape is changing, as according to the same SMMT figures just over 1200 plug-in vehicles were sold in March 2014 alone, adoption rates for the uptake of EVs to the mass market is still very low. A report for the European Council suggested that the main barriers for adoption were, high purchase price, range anxiety, uncertainties associated with battery life and other factors relating to new and unfamiliar technology (Wallis and Lane, 2013). Add to these the problems associated with users having to plug-in and charge the EV (as reported by Wellings et al., 2010), slow refuelling rates (Pearre et al., 2011), unwillingness to find alternative transportation if needed (Tamor et al., 2013), and the fact that charging cables do not respond well in extremes of hot or cold temperatures (Boys and Covic, 2013). Those who have driven an EV will also appreciate the associated inconvenience of having to interact with a potentially dirty, wet, heavy, inflexible cable in potentially wet, cold, icy environmental conditions, as well as the time taken to physically plug the vehicle in. Wireless charging could also reduce the accidental, or malicious, unplugging of a charging vehicle as there is no physical interaction point. All of the above factors equate to possible reasons why EV ownership has not taken off (as yet).

Whilst inductive charging will not physically increase the capacity of a battery, it may help remove the inconvenience factor of plug-in vehicles. Drivers will be able to just park their vehicle in a designated parking bay, and charging will begin automatically with no need to locate a cable and physically plug it in. A report by Carroll and Walsh (2011) suggests that ‘opportunity charging’, i.e. charging the vehicle little and often during the day when the EV is not in use, can lead to significant improvements in range compared to that available from a single overnight vehicle charge. This was as a result from being able to utilise over 100% of battery state of charge per day. Such opportunistic charging may be facilitated by the inherent ease and convenience associated with inductive charging systems.

A review of the literature reveals that limited research has been conducted into parking behaviour, which has been primarily focused on parking orientation and preferences (Cullinane et al., 2004; Kobus et al., 2012), gender differences (Wolf et al., 2010), desired clearance between vehicles (Gadgil and Green, 2005), parking related crashes and incidences (Green, 2006) or vehicle-to-vehicle gap in real-world parking (Thornton et al., 2014). The most relevant study for this current paper was conducted by Cullinane et al. (2004) whose research for the University of Michigan Transportation Research Institute (UMTRI) evaluated parking accuracy of 102 vehicles, in three different types of parking bays (angled, parallel and perpendicular). This was a retrospective analysis with participants not being aware that their parking would be assessed. Their research found no difference between the size of the vehicle and lateral parking accuracy, with drivers attempting to keep a constant amount of exit space on the drivers’ side of the vehicle in angled and perpendicular parking, and with parallel
parking the distance to the curb. However vehicle size did influence longitudinal clearance of perpendicular parking, with drivers more likely to overhang a ground barrier when parking a larger vehicle. The angle of parking tended to be quite small, generally less than $\frac{1}{4}$; however the range of angles was triple that for parallel parking verses angled and perpendicular parking (Cullinane et al., 2004).

As suggested above, it is well established that the efficiency of transfer of electrical energy through induction is highly reliant on alignment of the coils involved – in this case, the alignment between a primary coil in the parking space, and a secondary coil mounted on the vehicle. If the integration of inductive charging technology into modern vehicles is to be accepted by drivers, engineers should seek to minimise the amount of disruption to current parking behaviour. Therefore understanding the issue of parking misalignment and driver behaviour is an important human factors question, which can inform research and development in the area in order to improve the solution. However, research into this emerging technology is limited in the academic literature, and hence the focus of this paper.

2. Methodology

Two studies were conducted, one a retrospective analysis of 100 pre-parked vehicles where drivers were not aware that their parking alignment was going to be assessed when they originally parked. The second was a dynamic study where participants parked an EV aiming to align with a charging pad with no bay markings as guidance. For both studies the measure of parking accuracy, or success of the parking task, was defined by the position of the centre of the vehicle to the centre of the parking bay. This definition removed any vehicle or bay size effect from the comparative analysis.

The retrospective measurement methodology offers the benefit of naturalistic with real-world data being collected. However, it will not be able to determine the specific parking goal of the driver, or to what extent being aware their parking accuracy is being assessed will alter actual alignment. In addition no context was available as to why the driver chose to park as they did. It is entirely possible that drivers chose to park ‘misaligned’ either to allow sufficient space for them to exit the vehicle or gain access to the boot. It could be assumed that when users know they should be parking as accurately as possible, an improvement in both lateral and longitudinal control will be observed. This was the intention and purpose of the second, dynamic study.

2.1. Retrospective analysis

One hundred vehicles were randomly selected for measurement from three different car parks on the main campus of the University of Warwick. Vehicles were already parked when measurement were taken. Assessment took place over a two week period during July 2013, with physical measurements being taken between 10:00–12:00 and 14:00–16:00.

The three car parks selected for the study were all perpendicular bays, with a white ‘T’ to identify the front of the parking bay, and either a white dash or with no markings at the rear of the bay (Fig. 2). Irrespective of parking orientation the ‘front’ of the bay was always defined as the head or opening of the bay and identified with the white ‘T’. The rear of the bay was always identified as having a barrier beyond the parking area. This barrier would either be a ‘hard’ steel barrier or ‘soft’ shrubbery barrier. The full car park characteristics are outlined in Table 1 below:
2.2. Measured and derived variables

To measure the actual parking alignment of vehicles they were simply modelled as rectangles located in a rectangular bay. The principal method of data collection for determining parking bay and vehicle size was by physical measurement and other relevant observations. From this numerous different parameters (Fig. 3) could be derived, including:

**Measured Variables**

- **Length and width of parking bay**: These were measured by tape measure, from the back of the bay to the front (including line markings), and between the inside of both “T” or parallel marks.
- **The length, width and wheelbase of the vehicle**: These were measured by tape measure, between markers which were set down on the floor at the points at which the corners of the “vehicle” rectangle in the model would be located.
- **The distance from vehicle to side of bay**: Perpendicular distance from corner of the vehicle to the side of the parking bay, taken from the two opposing corners of the vehicle that were closest to the bay lines, made using a tape measure.
- **The closest distance between the vehicle and the rear of the bay**: Measured using a tape measure.
- **The orientation of the vehicle**: Reversed or driven in.
- **The general category of vehicle**: From a pre-determined list of types.
- **Parking aids**: If fitted, i.e. none, rear or both (front and rear).

**Derived Variables**

- **Location of the centre of the vehicle and parking bay**: Derived with respect to a coordinate system with origin in the centre of the bay.
- **Parking Angle** of the vehicle to the bay, in degrees.
- **Displacement** of centre of vehicle from the centre of the bay in both lateral (x) and longitudinal (y) axis, in cm.
- **Distance** of centre of vehicle from the centre of the bay in both lateral (x) and longitudinal (y) axis, in cm. Distance is the absolute value of the displacement, i.e. if they were away from the centre of the bay, then by how far.
- **Distance from Centre**: Distance the centre of vehicle is away from the centre of bay, in cm. As stated previously this is the primary measure for parking accuracy used in this study, and forms the basis of the statistical analysis.

2.3. Dynamic parking study

A second, pilot study was conducted to evaluate how participants parking accuracy was affected when they were aware of the aims of the study, i.e. to evaluate their accuracy when parking a Nissan Leaf EV over a simulated inductive charging pad (77 × 58 cm in size) with no bay marking. This scenario was established in order to gain a true understanding of parking accuracy with no barriers, markings or other vehicles to offer alignment guidance (Fig. 4). In addition this could be considered an appropriate scenario for charging on a driveway at home. Ten participants (five male and five female) took part in this dynamic study, with data collection taking place on a secluded section of private road on the main campus at the University of Warwick. The scenario started with the vehicle being parked at the approximate location of the red 4 ‘dot’ in

---

4 For interpretation of color in Fig. 4, the reader is referred to the web version of this article.
Fig. 4, from here the participant drove the vehicle down a short straight and turned left at the corner in order to align and park over the charging pad. The road was 5.6 m wide, with no marking apart from double yellow lines down both sides. The pad was located 2.4 m from the left edge of the road, and 3.5 m from the end of the road, i.e. not centrally which would have given the driver something to align the vehicle to when parking, ensuing it was a truly freeform parking scenario (Fig. 4). All of the participants were registered to drive a University owned vehicle on the Universities insurance policy, but were not experienced at driving the Nissan Leaf EV. For this reason a researcher was always present within the vehicle to advise on vehicle operation, give study instructions and deal with any questions surrounding the study.

Two conditions were adopted based on what part of the vehicle was being aligned over the target charging pad, these were either the ‘front’ or ‘centre’ of the vehicle. These were selected based on current locations of actual wireless charging demonstrator vehicles which have been produced. Participants were simply instructed to ‘park accurately with the front/centre of the vehicle over the charging pad’. The order that the two conditions were completed was randomised. Participants were allowed to manoeuvre the vehicle and make positional adjustments until they were happy with their final position. However, in practice all participants were satisfied at the first attempt. Parking accuracy was again assessed by physical measurement, as per the retrospective analysis, with the derived variables described previously being the principal measures.

2.4. Data collection and analysis

Raw data were collected via physical measurement with a tape measure, collated on a data entry sheet, and then transferred to IBM SPSS Statistics 21 for analysis. Data for vehicles which had been reversed into the parking spaces in the retrospective analysis were inverted for the analysis. Meaning that if the driver parked off-centre laterally (i.e. leaving more space either to the driver or passenger side) then this would not be lost in the analysis. A One-Way ANOVA was used to determine statistical significance, and was accepted at $p < 0.05$.

Ethical approval was granted for the study by the University of Warwick’s Biomedical and Scientific Research Ethics Committee (BSREC). For the retrospective analysis it was agreed that no identifying features of the vehicle would be recorded (e.g. photographs of assessed vehicles, number plates, gender of driver, etc.), and in the case of approach by a member of
public the researchers would offer a verbal and written explanation of the study, and give the opportunity for the driver of a measured vehicle to have their data removed.

3. Results

3.1. Retrospective analysis

Below are results from the objective measures of vehicle classification from the 100 vehicles analysed in the retrospective analysis. Table 2 shows that the majority of vehicles evaluated were hatchback, with no parking sensors and had been driven forward into the parking bay. Table 3 shows that on average vehicles tended to park towards the left of the bay (with an x-displacement of $-3.1$ cm), and the rear of the bay (y-displacement $15.6$ cm), regardless of orientation. The mean angle of parking was $0.02^\circ$.

Graph 1 in Fig. 5 shows the distribution of x and y coordinates of the centre of the 100 vehicles in this sample, coloured by size of vehicle (determined by separating the data equally into three groups, based on the area of the vehicle base, width $\times$ length). Statistical analysis showed that there was an overall significant difference in the data set ($F_{(2,99)} = 7.91$, $p < 0.001$), with post hoc analysis (Bonferroni corrected) showing that small vehicles were parked significantly less accurately (i.e. a greater ‘distance from centre’) than both medium ($p < 0.05$) and large ($p < 0.001$) vehicles, with no difference between medium and large ($p > 0.05$). Graph 2 illustrates parking accuracy in relation to orientation of parking (i.e. driven forward into the bay or reversed). There was no difference between the two orientations with respect to distance from the centre of the bay ($F_{(1,99)} = 0.10$, $p > 0.05$). Fig. 6 shows the distance to the rear of the parking bay (i.e. centre y-distance) for the different car park barrier types.

Parking aids are designed to assist specifically with the longitudinal aspect of parking. Results showed that parking sensors significantly ($F_{(2,89)} = 8.83$, $p < 0.001$) increased the accuracy, as defined by the distance of the centre point of the vehicle from the centre point of the bay, of parking alignment in this study (Fig. 7).

3.2. Dynamic parking study

Table 4 shows results from the dynamic study. Parking was generally more accurate in the lateral direction when aligning the front of the vehicle over the charging pad in comparison to the centre of the vehicle (mean x-displacement of $0.5$ verses $7.3$ cm respectively). This difference was statistically significant ($F_{(1,19)} = 9.02$, $p < 0.05$). As with the retrospective analysis, accuracy in longitudinal axis was again inferior, with drivers generally parking short of the charging pad target with both front (y-displacement = $-66.86$ cm) and centre ($-34.05$ cm) parking conditions. Interestingly though, the distance the centre of the car was away from the centre of the charging pad was similar for both conditions at approximately $75$ cm (Table 4).

4. Discussion

Two studies were conducted both with different objectives. The first a retrospective analysis of how people park with clear limiting variables such as bay markings and barriers, but not being aware that their parking was being evaluated. The second a free-form parking task, with only a $77 \times 58$ cm charging pad as a target. Understanding how people park in these two situations will offer important insights and help designers to develop enhanced inductive charging systems, which have the potential to facilitate the uptake and convenience of plug-in vehicles.

4.1. Retrospective analysis

The elliptical nature of the spread of data in Fig. 5, with the x-mean at approximately zero and y-mean at approximately $15$ cm, suggest that vehicles were parked more accurately in the lateral (or x) direction compared to the longitudinal (y) direction. The spread in the data also reflects this, with the range of lateral accuracy at around $60$ cm which was approximately half that of the longitudinal range. Table 3 shows that the mean lateral distance was $12.1$ cm (either to the left or right), with a mean displacement of $3.2$ cm to the left of the bay (i.e. more clearance on the driver compared to passenger side). Research conducted by Cullinane et al. (2004) showed that in a comparable study conducted in Ann Arbor, Michigan, US, vehicles were parked with an average of $10.4$ cm clearance on the drivers’ side (right in the case of the US). This increased lateral offset may be a function of the average bay width in the US study being $47$ cm wider than in the current study, or may simply be a cultural preference.

An assumption was made before the current study was conducted that larger vehicles would be less well aligned in the parking bay in comparison to smaller vehicles. This is based on the fact that they would have less space for movement and correction, or reduced visibility and perception of the front and rear of the vehicle due to the length. This was not borne out in the results as Fig. 5, graph 1, shows that the distribution of ‘large’ vehicles is more evenly spread around the centre of the bay, a difference which was significant ($p < 0.05$). Small vehicles in particular tended to park towards the rear of the bay compared to large vehicles. The spread of data in the lateral direction is similar for all sizes of vehicles. There is a systemic difference in the vehicles which may account for the accuracy differences observed. As we see in Fig. 7, the presence of parking
sensors increased the accuracy of parking alignment. Whilst parking sensors inform the driver of their distance to a rear barrier, and not the centre of the bay, the real-world application of this suggested that those without sensors were more likely to overhang the front of the bay or misjudge their longitudinal position within a bay. Therefore a secondary effect of parking sensors was better assessment of distance to rear barrier, which was directly linked to centrality within the bay. Of the 21 vehicles that had parking sensors, 13 were large vehicles with the remaining 8 medium sized vehicles. The four vehicles with front and rear sensors were all large vehicle, conversely no small vehicles had parking sensors fitted. Another possible reason for the increased ‘accuracy’ of larger vehicles is that the vehicle to bay ratio is smaller, meaning they have less space allowance to ‘play with’ when parking. Not parking centrally within a bay could increase the risk of the vehicle either overhanging the front or rear of the bay, both of which may result in physical damage to the vehicle. Smaller vehicles may choose to position themselves to allow for ease on exiting the vehicle, or choose to give a vehicle parked at the side more clearance and hence reduced risk of damage to their vehicle, but resulting in reduced accuracy. Cullinane et al. (2004) also found that vehicle size affected longitudinal accuracy, with drivers of a large vehicle more likely to overhang a ground (low) barrier.

An interesting occurrence was the adaptation to parking behaviours with the presence of a ‘hard’ rear barrier, in this case a steel structure in car park 8 (Fig. 2). Fig. 6 shows that the distribution of distance to rear of the bay when either a low or soft

</table>
40–50 cm, and may indicate the difficulty that people have judging the distance that their vehicle is away from the rear of the parking bay. It is at this point when in-vehicle feedback could be given to the driver to encourage more accurate longitudinal alignment.

The mean angle of parking was $0.02^\circ$, even in absolute form this was only $1.6^\circ$ (Table 3). Whilst this implies that in general vehicles were parked straight on in the bay, the range of the data again reveals greater differences of $15.8^\circ$ ($6.7$ to $-9.1^\circ$). Interestingly results from Cullinane et al. (2004) showed that whilst the mean angle was very small (and similar to the present study) at $0.1^\circ$, the range of the vehicles they recorded was significantly smaller at just $1.4^\circ$. This difference may be a function of the smaller number of vehicles evaluated parking in a bay (or perpendicular) with the Cullinane study (36 verses 100), or possible infrastructure aspects such as wider bays or expansive parking lots.

### 4.2. Dynamic parking study

Results from the dynamic study clearly show that parking alignment accuracy in the lateral direction was superior when drivers were ask to align the front of the vehicle over the charging pad (mean distance from centre = $5.9$ cm), compared to both dynamically aligning the centre of the vehicle ($13.2$ cm) and also assessed in the retrospective study ($12.1$ cm). The same was true for both displacement from the centre point and also reduced spread in the data assessed by standard deviation (Table 4). Fig. 8 shows this graphically for the dynamic study.

Reasons for the increased accuracy in the lateral direction when aligning the front of the vehicle over the charging pad may be the simple fact that the target location was out of the driver’s view for a shorter period of time. If driving forward for an additional $1.42$ m (the distance between the ‘front’ and ‘centre’ point of the vehicle evaluated in this study) any slight misalignment of the vehicle will be exaggerated. It can be calculated that even if the front of the vehicle is aligned with the centre of the charging pad, the angle of driving trajectory only needs to be off by $4^\circ$ for the centre point of the vehicle to be misaligned with the charging pad after $1.42$ m of travel. This highlights the sensitivity of trying to align a vehicle over a target which is out of the driver’s field of view.

An interesting occurrence is seen with longitudinal alignment, whilst the mean $y$-displacement that participants stopped short of the charging pad was smaller (although not significant, $p > 0.05$) when parking the centre of the vehicle over the charging pad compared to the front, at $-34.1$ to $-66.9$ cm, the mean distance (i.e. if there were away from the centre of the bay how far was this) was very similar at $74.7$ and $72.3$ cm respectively (Table 3). The standard deviations for $y$-displacement and distance in Table 3 show when aligning the front of the vehicle over the charging pad participants generally stopped short of it (Fig. 8; in fact only one participant overshot, compared to three with centre), they were far more consistent in their judgement of distance and needed only smaller longitudinal adjustments.

### 4.3. Inductive charging compatibility

An important consideration for this paper is the impact that parking alignment has on inductive charging systems in the real-world, and subsequently understanding the proportion of drivers who currently park within the tolerances of such systems. For this, two systems were considered; ‘System A’ has tolerances of $15$ cm in both the lateral ($x$) and longitudinal ($y$) axis and ‘System B’ $10$ cm in the $x$ and $20$ cm in the $y$ axis. The dimensions selected reflect two different approaches to coil design, and are representative of inductive charging systems currently on the market.

The data suggest, and Fig. 9 shows, that in both the dynamic and retrospective studies only $5\%$ of vehicles assessed in this paper parked within alignment tolerances for both inductive charging systems A and B. Meaning alignment of the two coils would not be sufficiently accurate to allow power transfer to be initiated at even a level of $80\%$ transfer efficiency. Fig. 9 also shows the range of alignment that developers of these systems for plug-in vehicles need to contend with, particularly in the longitudinal (or $y$) direction.

How to facilitate users to park within tolerances of inductive charging systems is a difficult human factors and engineering challenge; which cannot feasibly be solved by simply making the inductive coils larger. This is not a cost effective solution, also vehicle manufacturers will have packaging difficulties fitting a larger coil to the underside (and exposed aspect) of a vehicle. It may be addressed by technology, and specifically park assist systems. Results from this study showed that the presence of parking sensors on a vehicle significantly ($p < 0.001$) increased parking accuracy. Automated parking is already a feature on many premium vehicles, which could be used to park the vehicle accurately over the primary inductive coil in the bay. However, automated parking systems are a new and expensive technology which are typically only available for a limited range of parking manoeuvres. In addition it is still unclear if parking is considered as between two vehicles or two lines (namely the centre of the bay), as this will have an obvious effect on alignment.

A feasible solution would be to offer in-vehicle feedback to the driver during the parking manoeuvre. Results from the retrospective analysis showed that whilst parking is more accurate in the lateral direction, between $40\%$ and $50\%$ of vehicles parked were still outside $15$–$20$ cm alignment tolerances of the two real-world systems. Again only $40\%$ of participants parked within lateral alignment tolerances when aligning the centre of the vehicle during the dynamic study. This was entirely different with respect to front alignment, with only $1$ out of $10$ participants not being within the defined tolerances, and even this participant was only over by $1.2$ cm. Whilst results could suggest that presenting longitudinal (i.e. forward or backwards) information to the driver is only addressing half of the issue, lateral alignment accuracy is improved significantly by locating the vehicle mounted secondary coil towards the front of the vehicle. Results from this paper clearly show that...
longitudinal alignment (Fig. 8) is by far the greatest source of alignment inaccuracy and would benefit the most from in-vehicle feedback.

5. Conclusions

Whilst manufacturers claim inductive charging technology is market ready, the efficiency of transfer of electrical energy is highly reliant on accurate alignment of the coils involved, hence driver behaviour and parking alignment was the focus for this paper. Results from both the retrospective and dynamic studies suggest that drivers are more accurate at parking laterally than in the longitudinal direction. A reason for this may be that drivers can align the sides of the vehicle as a guide, whereas judging the position of the front or rear of the car is more difficult (without parking aids). Larger vehicles and the presence of parking sensors also had a significant positive effect on parking accuracy. Current inductive charging systems
typically have misalignment tolerances of approximately ±10 cm from their centre point. The distribution of parking accuracy observed in this paper were between 120 and 280 cm in the longitudinal direction and 20–60 cm laterally. This resulted in only 5% of vehicles in both studies being aligned sufficiently accurately to allow efficient transfer of electrical energy through induction.

Future research should be conducted to substantiate results from the dynamic study. This paper presents a ‘pilot’ analysis with only 10 participants, one parking scenario, and two conditions. Future research should focus on incorporating different parking tasks, such as parallel and bay parking, and also increasing the number of participants evaluated. Some unanswered questions still remain about the impact of vehicle size on parking accuracy. An interesting finding from this study was that larger vehicle parked more accurately (i.e. the centre of the vehicle was closer to the centre of the bay) compared to smaller ones; however, we were not able to determine if this was as a result of the presence of parking sensors on larger vehicles, or personal preference of smaller vehicle drivers to park ‘less accurately’.

5.1. Recommendations for future inductive charging systems

Based on results presented in this paper the authors have made some recommendations for consideration when designing future inductive charging systems or driver feedback systems, these are:

- Locate the vehicle mounted secondary coil towards the front of the vehicle in order to facilitate an increase in lateral alignment by the driver.
- In-vehicle feedback should focus on longitudinal advice as this is the greatest source of alignment inaccuracies.
- Longitudinal feedback should start to be given at approximately 50 cm prior to the target, as this is where a ‘second peak’ of parking misalignment occurred.
- A potential solution would be to offer lateral alignment advice at distances greater than 50 cm, then longitudinal feedback at less than 50 cm.
- Parking sensors should be adopted as they have a positive effect on parking accuracy.
- The combination of automated park assist and inductive charging would offer a ‘premium solution’ to the issues associated charging a plug-in vehicle.
